Posteriormente se calcularon los promedios de las calificaciones asignadas según cada uno de los criterios de la planilla, por cada uno de los grupos en cada instancia y el total. Si bien todos los promedios se observan entre los 3 y 4 puntos, se ve que el criterio que recibió las calificaciones más bajas fue C2: "Preparación y manejo de los contenidos al momento de desarrollar el trabajo". Mientras que la característica más valorada fue C1: "Respetó y consideró las ideas y opiniones de los demás". Estos resultados nos invitan a pensar que, durante el desarrollo del trabajo, los/as estudiantes le dieron mayor ponderación a aspectos grupales como el cumplimiento de las pautas establecidas, que a cuestiones individuales como lo es la preparación necesaria para abordar las consignas. Asimismo, en el gráfico de la Figura 1 se puede ver como varían las valoraciones de cada criterio de instancia a instancia y entre los grupos.

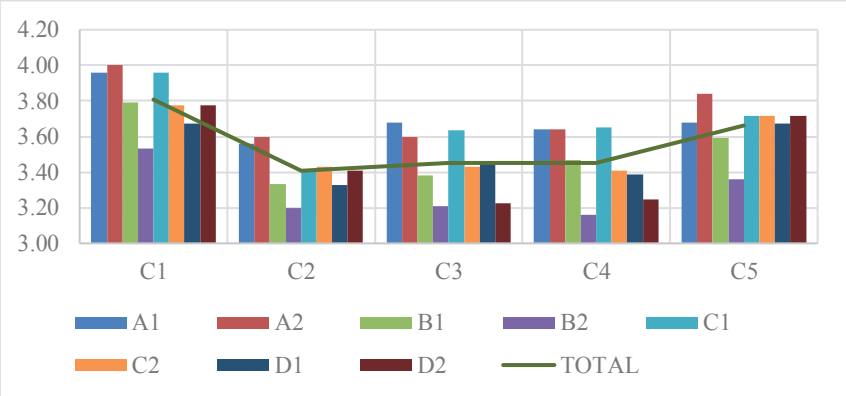

Fig. 1. Puntuaciones promedio por criterio de evaluación según cada grupo y en cada instancia. C1: "Respetó y consideró las ideas y opiniones de los demás"; C2: "Preparación y manejo de los contenidos al momento de desarrollar el trabajo"; C3: "Participación durante el desarrollo de la actividad"; C4: "Focalización e iniciativa en el desarrollo del trabajo."; C5: "Grado de integración de los demás miembros del grupo"

Análisis de los espacios de retroalimentación

Se explican a continuación los resultados obtenidos del análisis de las respuestas dadas en el espacio de retroalimentación. Primero se publican los establecidos en la coevaluación y luego en la autoevaluación.

Espacio de Retroalimentación en la coevalución

Se leyeron todas las respuestas que dejaron los/as estudiantes a sus compañeros en el espacio de "retroalimentación general" y se las clasificó según la orientación y según la intención. La orientación se refiere a quién es el sujeto de evaluación de lo escrito y se diferenciaron: retroalimentación particular, a las que daban un comentario que demostraba que era particular hacia esa persona que estaban evaluando; retroalimentación

general, los comentarios que no demostraban ser personales del/la compañero/a evaluado/a, sino que era general hacia el grupo o incluso los que se repetían de un/a mismo/a evaluador/a a todos/as sus evaluados/as; y retroalimentación vacía (Respuestas en blanco). Por otro lado, la intención de la retroalimentación significa cuál es el objetivo que persigue la misma. Estas pueden ser Evaluativas o Descriptivas. Dentro de las primeras encontramos elogios y enaltecimientos por realizar bien un rol o tarea y, por otro lado, críticas constructivas o recomendaciones. Las descriptivas se caracterizan por comentarios varios sin juzgar ni elogiar, o que indican qué rol ocupó en el grupo. En la Tabla 3 se muestran la contabilización de cada uno según cada grupo e instancia. En los Gráficos 2 y 3 se observa como la mayoría se trataron de retroalimentaciones particulares y de elogios, y resultó sumamente parejo entre las otras 2 categorías. Estos datos dan pie a concluir que han aprovechado los espacios de coevaluación, dedicándole tiempo y reflexión a esa tarea e inclusive dando recomendaciones o críticas constructivas a sus compañeros/as.

Tabla 3. Cantidad de tipo de retroalimentaciones según Orientación y según Intención

Grupo. Instancia	Orientación			Intención		
	Particular	General	Vacío	Elogio	Comentario	Crítica constructiva
A1	16	4	0	19	3	2
A2	9	7	4	20	0	0
B1	59	3	10	56	7	15
B2	35	14	23	31	8	12
C1	17	18	7	40	8	8
C2	10	26	6	39	2	1
D1	22	2	18	28	4	4
D2	18	6	18	25	2	1

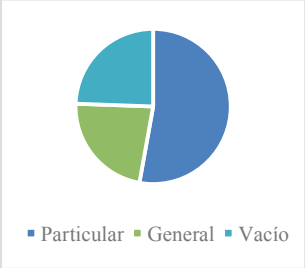

Fig. 2. Distribución de las retroalimentaciones según su orientación.

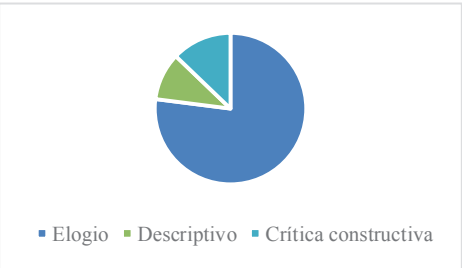

Fig. 3. Distribución de las retroalimentaciones según su intención

Espacio de retroalimentación en la autoevaluación

Del espacio de retroalimentación general de la autoevaluación, pudieron obtenerse conclusiones cualitativas respecto al funcionamiento interno de cada equipo. Es decir, en la reflexión interna que cada integrante realizó, pudieron reflejarse las situaciones particulares vividas en el equipo. Las mismas se enuncian a continuación para cada grupo:

Grupo A: Les costó encontrarse al principio, pero luego funcionó muy bien, sus integrantes se sintieron cómodos y hubo buena sinergia de grupo.

Grupo B: El funcionamiento respecto a la consigna aparenta haber sido bueno. Hay muchas reflexiones respecto a la importancia de la paciencia y la escucha de las opiniones de los demás, resaltando lo fundamental de dichas actitudes para una buena sinergia de grupo. En la segunda instancia, se destacan muchos comentarios respecto a la dificultad para coordinar el trabajo y hasta parece haber sido resuelta la consigna solo por una parte del grupo, con la no participación de algunos/as. Es interesante destacar que estas complicaciones dentro del grupo no se reflejan en las valorizaciones de la planilla (como puede verse en la Tabla 2, el promedio del Grupo B en el segundo trabajo práctico es de 3,36 puntos en la autoevaluación y 3,34 en la coevaluación), más bien son encontradas como comentarios en el espacio de retroalimentación.

Grupo C: El grupo afirma un muy buen funcionamiento, con desafíos a la hora de organizarse, pero luego logrando que sus integrantes se sintieran cómodos y resulte en una buena experiencia de trabajo.

Grupo D: Buen funcionamiento del grupo. Se destacan varias reflexiones respecto a la novedad de la experiencia de trabajar con personas desconocidas y de lo fortalecedor de la experiencia que les permitió poner a prueba timidez, opiniones de otros, organización virtual y comunicación en general.

Por otro lado, se sabe que trabajar en equipo supone el desarrollo de diversas capacidades como pueden ser: la habilidad para comunicar, un grado de conocimiento de uno mismo, la posibilidad de reflexionar y tomar distancia de las situaciones en que se inserta, tolerar la incertidumbre, saber escuchar, pensar que el otro puede aportar una idea, que no conocía, tener confianza en los otros, ser capaz de dialogar, intercambiar ideas y construir desde el consenso. La reflexión sobre el desarrollo de dichas capacidades ha quedado en evidencia en los espacios de retroalimentación de las autoevalauciones. Por ejemplo, el reconocimiento de las limitaciones o desafíos propios se expresan en comentarios como “Considero que me cuesta dar la iniciativa, pero una vez que se plantea el trabajo sigo el ritmo de mis compañeros, coordinando con ellos la realización y distribución de tareas”; “Creo que debo trabajar en fomentar la integración grupal y la distribución de tareas, y tratar de considerar opiniones”.

El saber escuchar y pensar que el otro o la otra puede aportar una idea se ve muy bien reflejado en las siguientes frases: “Trabajar de manera colaborativa con ellos me sirvió para confiar en que cada uno es capaz de cumplir con su parte, además pude trabajar la paciencia” ; “Mediar ideas enriquece de manera positiva gracias a los diferentes puntos de vista de cada integrante”; “Entendí que se puede trabajar en grupo, pero es de suma importancia la actitud de cada integrante, y es muy importante saber compartir y delegar responsabilidades”.

La autoestima en un grado adecuado es también una capacidad deseable en los integrantes de un grupo. En algunas frases se descubre como la autoestima ha sido reforzada gracias al trabajo en grupo realizado, como en "He logrado relacionarme de manera excelente con compañeros que no conocía" y "El trabajo en equipo fue muy bueno, hemos estado de acuerdo en las formas de su realización y todos hemos aportado dentro de nuestras posibilidades".

Por otro lado, los/as estudiantes también reconocen momentos de dificultad atravesados en el trabajo grupal. Esto puede considerarse natural porque no debemos olvidar que no todos/as los alumnos/as se inclinan con gusto hacia la participación en el trabajo en grupo. Básicamente, puede deberse a que no tienen intención de compartir sus ideas, esfuerzos y el resultado de su trabajo con otros/as, porque se resisten a colaborar en una producción que no les habrá de pertenecer en exclusividad. En algunos casos, se trata de personas con fuertes objetivos personales y en otros por considerar los trabajos grupales como una pérdida de tiempo, considerándose capaces de hacer solos la actividad indicada sin necesidad de reunirse con otros/as [22]. A esto puede sumarse la desconfianza creada en experiencias previas. Revisando las reflexiones, se encuentran las siguientes frases sustentando dichas dificultades: "Si bien participo y me esfuerzo mucho en la realización de los trabajos, haciendo las actividades como estudiando el material de lectura, creo que debo mejorar en el trabajo en grupo. Estar abierto a las opiniones de los demás y no solamente respetarlas, puesto que éstas son valiosas principalmente cuando nos interpelan". Por otro lado, conectando con la dificultad descripta previamente en el Grupo B, una de las personas integrantes expresa: "En un grupo hay integrantes que solo quieren hacer presencia, otros que quieren hacer cosas pero esperan que les digan que hacer y están los que directamente hacen y estos últimos perjudican a las demás en el sentido que no les dejan participar, integrarse, porque no entienden que trabajar en grupo es aceptar al otro, organizarse y preocuparse para que como grupo se avance sobre el tema. No se puede aprender bien el tema así de esta manera grupal y no me gusto esta modalidad que adoptan algunos integrantes". En este sentido, como sostienen Romero & Saune [21], el conflicto no solo es inherente al grupo sino que también es fundamental como motor de cambio, y consecuentemente, el proceso de resolución del conflicto es un proceso esencial de la dinámica grupal. Si este fuera un grupo que debiera perdurar por un mayor lapso de tiempo que el trabajado en este curso de 4 meses, indefectiblemente sus integrantes deberían evaluar sus actitudes para lograr un cambio que resuelva el conflicto existente.

Otra dificultad encontrada, fue la falta de preparación a las reuniones de trabajo: "Un aspecto a mejorar podría ser el funcionamiento de los encuentros, ya que en ocasiones experimentamos falta de ideas o trabas, momentos en los que nos encontrábamos todos conectados, pero tardábamos en encontrar una manera de resolverlo. Se entiende la importancia de haber leído previamente todo el material y de haber pensado algunas ideas o contribuciones para que el encuentro sea ágil y no se tenga que recurrir a la bibliografía por desconocimiento". Este comentario representa muchos otros que expresaban la misma idea respecto a la importancia de prepararse e interiorizarse respecto a la consigna y la temática previo al encuentro del grupo, para poder trabajar más ágilmente.

Además, está en línea con lo mencionado previamente en el análisis cuantitativo, referido a que el criterio de evaluación C2: "Preparación y manejo de los contenidos al momento de desarrollar el trabajo" haya recibido la menor valoración promedio.

Por último, como se mencionó previamente, la reflexión es una capacidad sumamente importante para la mejora del desempeño dentro de un grupo. Esto queda bien explicado en el siguiente comentario: "La posibilidad de reflexionar acerca del trabajo realizado ayuda a poner en palabra cuestiones a considerar su importancia y otras a revisarlas para poder aprender formas de mejorar. No es usual que tengamos espacios así en trabajos grupales. Es importante reflexionar sobre las prácticas realizadas para hacerlas más efectivas. Si uno no reflexiona lo que hace, generalmente lo repite mecánicamente sin ningún cambio y pierde la oportunidad de mejora."

3.3 Análisis de la encuesta final

A continuación, se exponen los resultados obtenidos de la encuesta realizada al final del curso. En primera instancia se describe como fueron valorados los cuestionarios de auto y coevaluación, y luego exponen los resultados y reflexiones respecto a la distribución de roles dentro de los grupos.

Valorización del cuestionario

Como se describió en la sección de Instrumentos, en la encuesta dada al final del cursado se les pidió que respondan a dos preguntas considerando una escala del 1 al 5, donde 1 corresponde a "No me sirvió nada" y 5 "Me sirvió mucho". Dichas preguntas y el promedio de sus respuestas se muestran en la Tabla 4.

Tabla 4. Promedios obtenidos en la valorización de los cuestionarios de auto y coevaluación, en la encuesta final del curso.

Grupos	¿En qué medida consideras que las auto y coevaluaciones sirvieron para mejorar tu desempeño en el grupo?	¿En qué medida consideras que las auto y coevaluaciones sirvieron para mejorar del desempeño en el grupo de tus compañeros?
A	1.40	1.40
B	3.67	2.56
C	3.17	3.17
D	4.00	3.60
Promedio	3.06	2.68

Puede verse que los grupos B, C y D consideran que las auto y coevaluaciones sirvieron en buena medida (mayor a 3 puntos) al mejoramiento del desempeño personal en el trabajo en grupo, y exceptuando el Grupo B, también contribuyeron a la mejora del trabajo de los compañeros.

La segunda pregunta tenía como objetivo principal analizar si el hecho de calificar a los compañeros según sus actitudes en un grupo representaría una manera de expresar sus disconformidades o deseos en caso de que el desempeño del grupo no sea bueno,

esperando así, que la persona cambie su actitud. En base a las respuestas dadas en la planilla, en muy pocos casos se registraron comentarios que indiquen que algún integrante del grupo no estaba trabajando de la manera esperada (1,3% como se dijo anteriormente). Sin embargo, observando las retroalimentaciones, en muchos casos sí se hacía referencia a dichas situaciones, pero normalmente se justificaba y se demostraba empatía con el/la compañero/a con comentarios como "no participó mucho, pero entiendo que no ha podido por sus exigencias laborales y familiares".

Observando y comparando los valores promedios de cada pregunta, se concluye que en general, el cuestionario contribuyó más a la mejora del propio desempeño (3.06 puntos) que el percibido en los compañeros/as (2.68 puntos).

Distribución de Roles

En esta última encuesta, también se indagó acerca de la distribución de roles dentro de cada grupo. Específicamente se preguntó quién consideraba que había desarrollado cada uno de los roles mencionados al principio, teniendo la opción de tildar a más de un/a compañero/a, además de la opción "TODOS/AS" y "NADIE". Los principales resultados que se obtienen de esta sección tienen que ver con las muchas diferencias de percepciones ocurridas. A continuación se detallan algunos ejemplos:

- Un mismo rol era tildado por algunos integrantes como que fue desarrollado por TODOS/AS, mientras que otros integrantes tildaban la opción de NADIE. Sucedió en el rol de *Moderador de la dinámica grupal* y en el de *Evaluar el cumplimiento de las consignas*. Seguramente esta controversia pueda deberse a una interpretación distinta en cada caso. Por ejemplo, la persona que señaló la opción de NADIE pudo haber querido decir que nadie específicamente cumplió ese rol, es decir, que todos/as lo hicieron a su manera y tiempo, por lo que así, podría suponerse que hay coincidencia en la respuesta TODOS/AS.
- La gran mayoría del grupo atribuyó un rol a una persona y esa persona no se lo atribuyó.
- No hubo ni un caso en donde todas las respuestas coincidieran.

Otra pregunta de dicha sección fue si consideraban que se había desarrollado algún otro rol además de los especificados. La mayoría de las respuestas fueron NO, mientras que algunas de las respuestas no respondían al concepto de rol o se encontraban dentro de alguno de los roles ya establecidos. Los roles que podrían considerarse adicionales son:

- Persona intermediaria con las docentes: Quién hacia las preguntas cuando surgían dudas específicas de las consignas.
- Persona que facilitó las cuestiones técnicas: quien se grabó las clases de la materia, quien edito el video, programaba las reuniones virtuales, etc.

Asimismo, se preguntó cuál era el rol que consideraba personalmente que mejor y más había desarrollado en el grupo, dando como opciones los roles establecidos inicialmente y la opción libre "otro" para que expliquen cual. A continuación, se muestran las

respuestas de cada grupo, y la general que incluye todas las respuestas, en el conjunto de gráficos de la Figura 4. Se observa como en todos los grupos predominaron las personas que se identificaron mejor con el rol de buscar información y aportar nuevas ideas (color verde). En segundo lugar, se destaca el rol de evaluar el cumplimiento de las consignas y realizar críticas constructivas al trabajo realizado (color azul). Solamente en un grupo se reconocieron personas como moderadoras de la dinámica del grupo (Grupo A) y personas encargadas de escribir las respuestas y pasarlas en limpio (Grupo D).

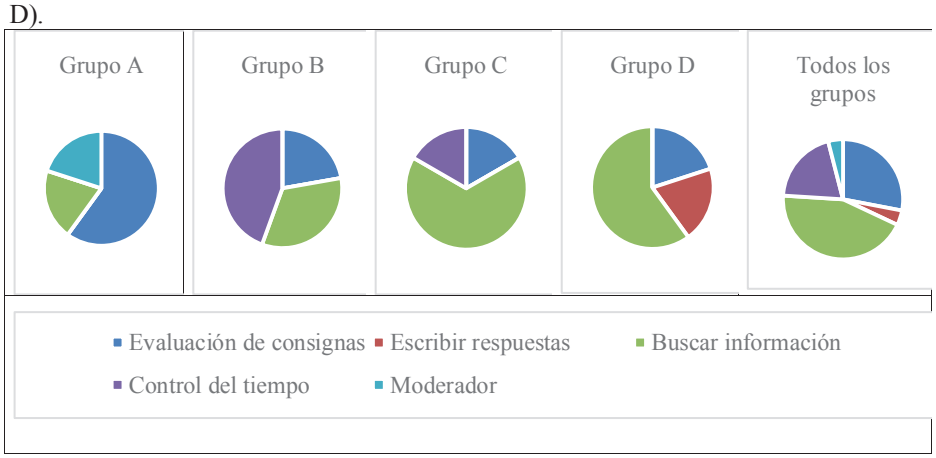

Fig. 4. Roles que los integrantes consideraron personalmente que mejor y más habían desarrollado en el grupo

4 Conclusiones y trabajos futuros

En el presente trabajo se detalló un procedimiento para alcanzar el objetivo de aprendizaje de aprender a trabajar en grupo, habilidad y competencia crecientemente demandada en el mundo laboral, principalmente en Ingeniería. La propuesta se basó en generar instrumentos y espacios para la autoevaluación y evaluación entre pares, dentro del trabajo grupal. La misma se desarrollado en un curso específico, en contexto COVID-19, pero puede ser perfectamente replicable y adaptable a cualquier otra clase. Partiendo de la generación de grupos aleatorios, consensuando las pautas de trabajo dentro de los grupos, estableciendo los criterios de evaluación de la cátedra, de auto y coevaluación y proporcionando para ello, instrumentos de muy sencillo uso, pudieron generarse instancias de importantes reflexiones tanto para los integrantes de cada grupo como para la cátedra docente.

Sabemos que uno de los objetivos de la educación superior es generar competencias en los estudiantes para el desarrollo profesional. Sin embargo, algunos autores sostienen que las competencias solo se adquieren en la práctica y por ello la controversia de la posibilidad o no del egreso de personas competentes, principalmente, porque trabajar en entornos reales no siempre es posible. Igualmente, la educación universitaria puede proporcionar a los/las estudiantes experiencias cercanas a la realidad para aprender a enfrentar los desafíos que se viven en los entornos reales, a través de herramientas como

el estudio de casos y el juego de roles. Estas fueron utilizadas por la cátedra persiguiendo el objetivo de acercar a los/las alumnos/as a situaciones posibles y potenciales de sus futuros entornos laborales, a la vez de que son herramientas que ajustan muy bien con la modalidad virtual y el proceso de enseñanza aprendizaje.

Si bien el promedio de las calificaciones de todos los criterios, tanto de las autoevaluaciones como de las coevaluaciones, fueron buenas o muy buenas, el espacio de devolución y retroalimentación fue aprovechado, dedicándole tiempo y reflexión a esa tarea e inclusive dando recomendaciones o críticas constructivas a sus compañeros/as. De hecho, en un grupo, una de las instancias de trabajo parece haber sido resuelta por solo una parte del grupo, es decir, no hubo una participación completa de todos sus miembros, pero sin embargo, esto no se refleja en las calificaciones de la planilla de co-evaluación, sino que aparece como autocrítica de parte de algunas personas o como comentario de retroalimentación entre pares. Esto nos invita a pensar acerca de que, si bien las coevaluaciones no significaban una ponderación directa en la nota final del curso, es decir, no se trataba de una evaluación sumativa sino formativa, igualmente los y las estudiantes lo vivieron como una instancia de calificación, con prudencia a la hora de marcar un error o una actitud no favorable para el grupo. Es decir, considerando al error como una falla y no como una oportunidad de mejora y aprendizaje. En experiencias futuras, consideramos que es importante trabajar con los/as estudiantes, los distintos conceptos de error, procurando generar pensamientos que reconstruyan la mala fama que dicho concepto tiene asociada.

Por otro lado, en este trabajo quedó en evidencia la importancia de generar espacios de reflexión y autoevaluación en los y las estudiantes, como medio para el desarrollo de habilidades de conocimiento propio, reconociéndose como sujetos dentro de un grupo, con virtudes y debilidades que significan oportunidades de mejora.

Por último, del análisis de la sección de distribución de roles de la encuesta se desprenden dos conclusiones importantes:

- En futuras experiencias debe reforzarse el significado de rol dentro de un grupo, para mejorar la lectura del desarrollo o no de los mismos. El hecho de que nadie se haya autoreconocido en otro rol fuera de los establecidos inicialmente, y que sí los hayan propuesto para otros miembros del grupo, sumado a la gran variedad de respuestas en las asignaciones, indicaría que les resultó más fácil detectar el rol que desarrolló uno/a mismo/a que el que desarrolló un/a compañero/a.
- Que no se haya identificado cada rol con una persona unánimemente habla de que los grupos no alcanzaron a consolidarse. Como se dijo en la introducción, un grupo no es solo un conjunto de personas, sino que debe existir una trama vincular y una historia compartida, fundada en base a un objetivo en común. En este caso, podría hablarse de que hubo *grupalidad*, un conjunto de personas con la potencialidad de convertirse en grupo [23].

Abstract. Para medir el conocimiento adquirido por un estudiante sobre un conjunto de objetivo de aprendizaje dado, es necesario realizar una evaluación. En general, en los colegios se utilizan pruebas estandarizadas para realizar esto. Sin embargo, este tipo de evaluaciones no logra captar el real conocimiento de los estudiantes sobre un conjunto de objetivos de aprendizajes determinado. En el presente trabajo se propone un nuevo método para realizar test que se adapten a los conocimientos de los estudiantes. Para ello, se consideran la relación entre los distintos objetivos de aprendizaje y la información histórica de un banco de preguntas.

Keywords: test adaptativo, modelo matemático, educación

1 Introducción

Actualmente existe una diversidad de aplicaciones o páginas (e.g., Duolingo, Coursera) que dictan cursos de diversas materias. Para evaluar a los usuarios, en general, utilizan test que se adaptan al nivel de conocimiento de ellos. Para realizar esto, en general, utilizan la información de evaluaciones previas para saber que preguntas asignar.

En términos pedagógicos cada unidad académica posee un conjunto de ejes de aprendizajes (e.g., operaciones matemáticas) y cada eje contiene un conjunto de objetivos de aprendizajes (eg., suma, multiplicación, potencias) que dependen del nivel que se esté cursando. Teóricamente existe una relación entre cada objetivo de aprendizaje. Por ejemplo, para saber multiplicar se debe saber anteriormente sumar y a su vez multiplicar se debe saber antes de las potencias. De este modo podemos definir, para cada objetivo de aprendizaje, un conjunto de objetivos de aprendizajes antecesores y sucesores.

Si bien este tipo de aplicaciones han proliferado en los últimos años, aún no se incorporan dichas tecnologías a los colegios. Tanto como para los administradores de los colegios como los profesores es importante tener conocimiento del aprendizaje obtenido por los estudiantes. Por un lado, a los educadores les permite conocer los niveles de conocimiento de sus estudiantes y con ello buscar las mejores estrategias para continuar con sus clases, y por otro lado les sirve a los administradores para evaluar el desempeño de sus profesores.

En general, para cumplir con esto se realizan evaluaciones periódicamente para saber si los estudiantes han aprendido la materia estudiada. Sin embargo,

muchas veces estas pruebas son estandarizadas, no logrando describir realmente los conocimientos de cada estudiante. Por esta razón, actualmente los educadores buscan nuevas metodologías de evaluación. Entre estas se encuentran los llamados test adaptativos los cuales van realizando preguntas considerando las respuestas previas del estudiante. Este tipo de test permite conocer de mejor manera el real nivel de conocimiento adquirido por cada estudiante. Por ejemplo, podemos permitir que el test considere objetivos de aprendizajes previos del conjunto considerado, de tal manera de determinar los objetivos aprendizajes antecesores que no ha alcanzado a adquirir un estudiante con mal rendimiento.

En el presente trabajo presentamos un nuevo método para desarrollar test adaptativos dirigido especialmente a colegios. El método consiste en tres etapas: primero construir un índice que permita relacionar los diferentes objetivos de aprendizaje, segundo construir un grafo de relación entre objetivos de aprendizaje y tercero construir grafo entre un banco de preguntas y los objetivos de aprendizaje, el cual se utilizará como input para el test adaptativo.

2 Definición del problema

Considere la materia de matemática. Sea $\mathcal{T}$ el conjunto de tipo de enseñanza (e.g., primaria, secundaria). Para cada tipo de enseñanza $t \in \mathcal{T}$ existe un conjunto de niveles $\mathcal{N}_t$. Cada dupla de tipo de enseñanza, nivel (t, n), $t \in \mathcal{T}, n \in \mathcal{N}_t$ existe asociado un conjunto de unidades $\mathcal{U}_{t,n}$, donde cada unidad $u \in \mathcal{U}_{t,n}$ tiene un conjunto de objetivos de aprendizaje $\mathcal{O}_u$. Asimismo, cada objetivo de aprendizaje $o \in \mathcal{O}_{t,n}$ tiene un único eje de aprendizaje.

Sea $\mathcal{P}_y$ el conjunto de preguntas confeccionada en el año y. Cada pregunta $p \in \bigcup_y \mathcal{P}_y$ aborda un único objetivo de aprendizaje o^p. Se asume que cada pregunta presenta un valor de "dificultad" de valor f^p.

Considere que se sabe teóricamente que cada objetivo de aprendizaje $o \in \bigcup_{t,n} \mathcal{O}_{t,n}$ posee un conjunto de objetivos de aprendizaje predecesores $\mathcal{B}_o$ y un conjunto de objetivos de aprendizaje sucesores $\mathcal{A}_o$. Sea $\mathcal{P}_y^o$ el conjunto de preguntas confeccionada en el año y que abordan el objetivo o.

Por conveniencia, se denota $p(1)$ si la respuesta la pregunta p es correcta y $p(0)$ otro caso. Asuma que existe una gran cantidad de datos disponibles, tal que, es posible estimar la probabilidad condicionada $\Pr(p(1)|p'(1))$ -esto es la probabilidad de contestar bien la pregunta p dado que contesto bien la pregunta p', donde $p \in \bigcup_y \mathcal{P}_y^o$ y $p' \in \bigcup_y \mathcal{P}_y^{o'}$ con $o' \in \mathcal{B}_o$.

El problema del diseño de una evaluación adaptiva desde un banco de preguntas se define como sigue. Considere un conjunto de estudiantes $\mathcal{S}$, un conjunto de preguntas $\bigcup_y \mathcal{P}_y$ que abordan un conjunto de objetivo de aprendizaje $\bigcup_{t,n} \mathcal{O}_{t,n}$. Dado un estudiante $s \in S$ y un objetivo específico o, se desea determinar el conocimiento de los objetivos de aprendizaje en matemáticas por parte de un estudiante $s \in S$ a través un subconjunto de preguntas J_s de cardinalidad mínima.

3 Método inteligente y aplicación para la generación del test adaptativo

En esta sección se formula un método inteligente que permita la generación del test adaptativo. Este método basado en un modelo matemático el cual asume el análisis y el precálculo de: 1) la correlación entre las preguntas según los datos históricos disponibles del desempeño para un conjunto de estudiantes, 2) un grafo parcial de las relaciones entre los objetivos de aprendizaje, y 3) la estimación de la dificultad de la pregunta dentro del conjunto de preguntas que abordan el mismo objetivo según una métrica establecida por algún método psicométrico.

Nuestro método adopta la teoría de espacio del conocimiento [3, 5], buscando determinar las relaciones entre todas las preguntas considerando que cada pregunta aborda un objetivo de aprendizaje específico el cual posee *a priori* un conjunto de objetivos de aprendizaje sucesores y predecesores, maximizando la suma de las correlaciones obtenida por las selección de las relaciones determinadas entre preguntas.

Para ello, presentamos dos modelos matemáticos que ayudan a determinar dichas relaciones. Primero realizamos un modelo que relaciona objetivos de aprendizaje con objetivos de aprendizaje, el cual determian el conjunto de sucesores y antecesores de cada objetivo de aprendizaje. El segundo, determina la relación entre preguntas y objetivos de aprendizaje de este modo una pregunta $p \in o$ es asociada a un $o' \in \mathcal{B}_o \cup \mathcal{S}_o$.

3.1 Modelo pregunta-objetvo

Consideremos que el estudiante se encuentra en la pregunta $p \in \mathcal{P}_y$ que aborda el objetivo de aprendizaje $o^{\mathcal{P}}$. Si el estudiante responde correctamente, se continuará evaluando otro objetivo de aprendizaje que se encuentre dentro de los sucesores del objetivo de aprendizaje $o^{\mathcal{P}}$. Entonces se le asignará una pregunta $p^{'}$ correspondiente a un objetivo aprendizaje $o^{'} \in \mathcal{S}_o$. En caso que responda incorrectamente, se evaluará un objetivo que pertenzca al conjunto de predecesores $\wr$. Entonces, se le asignará una pregunta $p^{'} \in \mathcal{B}_o$). El siguiente modelo construye un grafo entre preguntas y objetivos de aprendizaje. La idea es que cada pregunta se conecte con un objetivo de aprendizaje perteneciente a los sucesores del objetivo de aprendizaje de la pregunta, y con un objetivo de aprendizaje perteneciente a los predecesores del objetivo de aprendizaje actual. Dicha conexión se realizará siempre y cuando la pregunta p tenga una correlación mayor a un paramétro K con las preguntas pertenecientes al objetivo de aprendizaje $o^{'} \in \mathcal{S}_o$. Para ello, definimos una variable binaria $x_{p,o'}$ que será 1 si la pregunta $p \in \mathcal{P}_y$ que aborda el objetivo de aprendeizaje $o^{\mathcal{P}}$ se une con el objetivo de aprendizaje $o^{'} \in \mathcal{S}_o \cup \mathcal{B}_o$. Por comodidad definimos $w_{pp'} = \sum_{p \in \cup_y \mathcal{P}_y^o} \sum_{p' \in \cup_y \mathcal{P}_y^{o'}} \Pr(p(1)|p'(1))/|\mathcal{P}_y^o|$.

$$\max \quad \sum_{o \in OA} \sum_{p \in \mathcal{P}_o} \sum_{o' \in \mathcal{B}_o \cup \mathcal{S}_o} x_{po'} w_{pp'} \tag{1}$$

$$\text{s.a.} \quad \sum_{o' \in \mathcal{B}_o} x_{po'} \leq 1 \qquad p \in \mathcal{P}_o, o \in OA \tag{2}$$

$$\sum_{o' \in \mathcal{S}_o} x_{po'} \leq 1 \qquad p \in \mathcal{P}_o, o \in OA \tag{3}$$
$$\sum_{o' \in \mathcal{S}_o} x_{po'} w_{pp'} \geq K \qquad p \in \mathcal{P}_o, o \in OA \tag{4}$$
$$\sum_{o' \in \mathcal{B}_o} x_{po'} w_{pp'} \geq K \qquad p \in \mathcal{P}_o, o \in OA \tag{5}$$
$$w_{po'} \geq \sum_{o'' \in \mathcal{S}_o} w_{po''} x_{po''} \qquad o \in OA, o^{'} \in \mathcal{S}_o, p \in \mathcal{P}_o \tag{6}$$
$$x_{po'} \in \{0,1\} \qquad o \in OA, p \in o, o' \in B(o) \cup S(o) \tag{7}$$

La restricción (2) y (4) asignan a lo más un predecesor y un sucesor a cada pregunta $p \in o$. En tanto la restricción (4) y (2) permiten que exista arista entre una pregunta p y un $o \in \mathcal{B}_o$ y un $o \in \mathcal{S}_o$ siempre y cuando la suma de $w_{pp'}$ sea mayor al umbral K.

3.2 Modelo objetivo-objetivo

Existe una sucesión de objetivo de aprendizaje que es dada por expertos. Con los datos históricos podemos chequear, si esta sucesión es correcta; o si las preguntas estan correctamente etiquetadas. Para ello, desarrollamos un modelo de programación matemática que establece las sucesiones (o caminos) de aprendizaje dada la respuestas de los estudiantes en las pruebas anteriores. El modelo sigue la misma lógica anterior. Si dos objetivos tienen una correlación mayor a un paramétro L dado y esta es la mayor entre todas las alterntivas se hace la conexión. Ahora bien, la medida de correlación la asumiremos como un operador $T(P_o, P_{o'})$.

$$\max \qquad \sum_{o \in OA} \sum_{o' \in OA \setminus \{o\}} y_{oo'} T(P_o, P_{o'}) \tag{8}$$
$$\text{s.a.} \qquad \sum_{o' \in OA \setminus \{o\}} y_{o'o} \leq 1 \qquad o \in OA \tag{9}$$
$$\sum_{o' \in OA \setminus \{o\}} y_{oo'} \leq 1 \qquad o \in OA \tag{10}$$
$$\sum_{o' \in OA \setminus \{o\}} y_{oo'} T(P_o, P_{o'}) \geq L \qquad o \in OA \tag{11}$$
$$\sum_{o' \in OA \setminus \{o\}} y_{oo'} T(P_o, P_{o'}) \geq L \qquad o \in OA \tag{12}$$
$$y_{oo'} \in \{0,1\} \qquad o \in OA, o' \in B(o) \cup S(o) \tag{13}$$

La resolución de estos modelos matemáticos puede ser llevada a cabo a través del uso de métodos de optimización combinatoria Inicialmente se adopta un enfoque basado en un algoritmo exacto y heurístico que permite la resolución del problema [4]. Para calibrar y estudiar la eficiencia del modelo se desarrolló un simulador de test que utiliza la información histórica de pruebas anteriores. Los resultados muestran, que el método se puede adaptar a diferentes diseños de test; segundo, que se puede obtener mayor información de los conocimientos de los estudiantes con test que se adapten a cada estudiante. Finalmente, el propósito del método presentado, es servir como herramienta para profesores y directores de establecimiento que faciliten el desarrollo de nuevas estrategias pedagógica adaptadas al conocimiento de cada estudiante.

Abstract. Este artículo tiene como objetivo minimizar la distancia total recorrida para el problema del ruteo del picking (PRP), considerando almacenes 2D de múltiples bloques. Para esto, se formulan las distancias mínimas entre cada par de posiciones de almacenamiento a visitar en un tour, y se propone un algoritmo de optimización por colonia de hormigas (ACO), al cual se le realiza un ajuste de parámetros para garantizar un mejor desempeño para solucionar el PRP. Con base en experimentos computacionales, se establece que el ACO propuesto brinda soluciones de alta calidad y genera ahorros satisfactorios frente a una metaheurística y dos heurísticas ampliamente utilizadas para el PRP, requiriendo tiempos de computación viables para ambientes de simulación y ambientes de operación real de almacenes y centros de distribución.

Palabras clave: Preparación de Pedidos, ACO, Ruteo del Picking, Almacenes Multibloque, Metaheurísticas

1 Introducción

Los almacenes y centros de distribución (CEDIS) son componentes esenciales para la gestión de la cadena de suministro y la logística debido a que afectan significativamente el servicio al cliente, los costos y la eficiencia de toda la cadena de suministro [1], y representan alrededor del 20% de los costos totales de esta. Dentro de las operaciones de los almacenes y CEDIS, la preparación de pedidos (picking) es la más costosa al representar 50%–70% del costo operativo total de un almacén [2]. En consecuencia, es prioritario minimizar distancias y tiempos de recorrido [3], debido a que representan más del 50% del costo del picking, y aproximadamente el 90% del tiempo total de picking [4]. Por otro lado, dentro de las configuraciones de los almacenes, la consideración de múltiples pasillos transversales permite aumentar la eficiencia de los recorridos del picking [5], disminuyendo la distancia recorrida necesaria para cambiar de un pasillo a otro.

A pesar que muchas metaheurísticas se han presentado en la literatura, la optimización por colonia de hormigas (ACO) es la metaheurística más popular para solucionar el PRP [6], y brinda mejor desempeño que otras metaheurísticas para diferentes tipo de TSPs [7]. Entre los estudios que más se destacan para solucionar el PRP a través del ACO en almacenes 2D de múltiples bloques, no se modelan las distancias entre cada par de posiciones de almacenamiento que pertenecen a un mismo bloque o a múltiples bloques, por lo cual no se garantiza que el tiempos y distancia de recorrido entre cualquier par de posiciones a visitar en un tour sea mínima. Este estudio ofrece una formulación de distancia de recorrido adaptada para configuraciones de almacenes de múltiples bloques 2D.

2 Definición del Problema

El PRP para almacenes 2D, al clasificarse como un Steiner TSP, puede formularse como un TSP clásico si se calculan previamente las distancias mínimas entre cada par de ubicaciones de almacenamiento i y j (d_{ij}), lo cual se puede lograr a través de matrices de distancia entre todas las posiciones de almacenamiento. Para esto, dadas dos posiciones de picking $i = (x_{\mathrm{i}}, y_{\mathrm{i}})$ y $j = (x_{\mathrm{j}}, y_{\mathrm{j}})$, la distancia de Manhattan d_{ij} entre *i* y *j* tal que $1 \leq i \neq j \leq L$ se calcula a través de la Ecuación (1) cuando *i* y *j* pertenecen al mismo pasillo y bloque. La Ecuación (1) igualmente se utiliza cuando *i* y *j* pertenecen a diferentes bloques, indiferente del pasillo en que se encuentren. Cuando *i* y *j* pertenecen a diferentes pasillos en el mismo bloque, la Ecuación (2) se emplea, garantizando las distancias mínimas entre *i* y *j*.

$$d_{ij} = |x_i - x_j| + |y_i - y_j| \tag{1}$$

$$d_{ij} = |x_i - x_j| + min\{|y_i - T| + |T - y_j|, |y_i - F| + |F - y_j|\} \tag{2}$$

Para formular el modelo matemático del PRP, se considera un conjunto *L* de posiciones de almacenamiento, un subconjunto *S* de posiciones de almacenamiento, d_{ij} como la distancia mínima entre dos posiciones de almacenamiento *i* y *j*. La función objetivo minimiza la distancia total recorrida, y las restricciones aseguran que cada posición de almacenamiento pueda visitarse a lo sumo una vez en cada ruta, garantizan solo un predecesor y sucesor a cada posición de almacenamiento, evitan cualquier sub-tour para que las soluciones representen un solo tour, y definen las restricciones de dominio de las variables.

3 Optimización por Colonia de Hormigas

El ACO fue diseñado para solucionar el TSP con el fin de encontrar una longitud cíclica mínima para visitar un nodo cada vez, dado un conjunto de *n* nodos, donde d_{ij} representa la distancia entre el nodo *i* y el nodo *j*, y η_{ij} representa la visibilidad del arco *ij*, que permite elegir con mayor probabilidad al arco ij que tengan mayor visibilidad. Al inicio del ACO, todos los arcos ij tienen la misma cantidad de feromona $\tau_{ij} = \tau_0$, y se lanzan

K hormigas a recorrer la red de nodos, partiendo del nodo origen (Depot). Cada hormiga busca su propio recorrido, de tal forma que cada hormiga k al estar en un nodo *i* elige pasar a otro nodo *j* según una probabilidad definida P_{kij}, que depende de la distancia d_{ij} y de la cantidad de feromona presente en el arco *ij* (τ_{ij}).

El ACO brinda memoria a cada hormiga (M_k) a través de una lista tabú que guarda los nodos que ha visitado la hormiga k y prohíbe volver a estos nodos hasta que se completa un viaje, garantizando siempre soluciones factibles. Se termina un ciclo en el algoritmo cuando todas las hormigas han realizado un recorrido completo, y luego de esto se calcula la longitud del camino más corto encontrado entre todas las hormigas. Con esta información se actualiza el valor de la feromona τ_{ij} en cada arco *ij* al reducir dichos valores a través de la evaporación de feromona, y al aumentar la cantidad de feromona de los arcos que componen la ruta más corta encontrada entre todas las hormigas. Luego de que se completa un ciclo en el que todas las hormigas han construido una ruta factible, el proceso del algoritmo se repite hasta alcanzar el máximo número de iteraciones planificadas.

4 Experimentos

Se realiza un ajuste de parámetros para garantizar un mejor desempeño para solucionar el PRP, a través de 2 x 3 x 2 x 2 = 24 escenarios que corresponden a (α,β)×ρ×*K*×iteraciones, y en cada escenario se ejecutan 10 réplicas, generando así 240 corridas experimentales. Igualmente, se evalúan diferentes valores de τ_0 para establecer la feromona inicial. Como resultado, los valores parámetros sugeridos para el ACO propuesto son α=1, β=5, ρ=0.7, *k*=20, *iter*=30, $\tau_0 = \tau_{ij}(0) = \eta_{ij}$, garantizando un mejor desempeño en distancia recorrida y menores tiempos de computación para el algoritmo. Se adicional también el operador de cataclismo se utiliza para mejorar la eficiencia del ACO y evitar óptimos locales.

Una vez establecidos los parámetros del ACO, se realizan los experimentos para establecer el desempeño del algoritmo bajo diferentes escenarios de operación, y frente a la distancia recorrida que ofrecen otros métodos de ruteo del picking que se utilizarán como *benchmarks* tales como la heurística S-shape, la heurística Aisle-by-Aisle y los algoritmos genéticos (AG), de los cuales se toman los parámetros y operadores propuestos por [8]. Los escenarios se componen por el número de posiciones de almacenamiento a visitar (10, 20, 30) que se eligen aleatoriamente en cada corrida, número de pasillos del almacén (5, 10, 20), número de posiciones de almacenamiento por lado de cada pasillo (5, 10, 20), y número de bloques del almacén (2, 3), para un total de 3 x 3 x 3 x 2 = 54 escenarios, y en cada escenario se corrieron 10 réplicas del ACO, para un total de 540 corridas experimentales. Se aclara que se crean instancias propias de experimentación, debido a que instancias conocidas como las de [9] ofrecen instancias experimentales para almacenes con dos bloques y tres pasillos transversales, pero no para almacenes de tres bloques y cuatro pasillo transversales, tal y como se requiere para este estudio.

5 Resultados

Con base en los experimentos realizados, el ACO ofrece ahorros en promedio del 7.7%, 15.1%, y 22.8% frente al AG, S-shape y Aisle-by-Aisle respectivamente. Igualmente, se identifica que el ACO ofrece ahorros de hasta el 21.0% frente al AG, ahorros de hasta el 36.1% frente a la S-shape, y ahorros de hasta el 43.6% frente al Aisle-by-Aisle. Del mismo modo, el ahorro del ACO en distancia recorrida frente al Aisle-by-Aisle y S-shape incrementa a medida en que se requiere visitar un menor porcentaje de las posiciones del almacén en un tour (posiciones a visitar / posiciones de almacenamiento). El efecto del número de bloques sobre el desempeño del ACO evidencia que a mayor número de bloques se obtiene mayores ahorros por parte del ACO frente al AG, S-shape y Aisle-by-Aisle, demostrando la eficiencia del algoritmo propuesto para almacenes multibloque. En este sentido, al pasar de 2 a 3 bloques, el ACO aumenta 2.7 veces el ahorro frente al AG, aumenta 1.9 veces frente al S-shape y 1.6 veces frente al Aisle-by-Aisle.

Para validar la significancia de los resultados obtenidos, se aplica una prueba *t* de *Student* con la cual se identifica que la media de la distancia recorrida del ACO es significativamente menor (a un nivel de confianza del 95%, valor-p < 0.05) a la media brindada por la heurística S-shape y Aisle-by-Aisle, lo cual va en línea con los mayores ahorros en distancia recorrida identificados previamente. Al comparar la media del ACO con la media del GA no se obtienen diferencias significativas a un nivel de confianza del 95%, lo cual representa que ambos métodos son eficientes para solucionar el PRP, sin embargo, se recomienda el uso del ACO al brindar frente al GA ahorros en distancia recorrida de hasta el 21%.

En cuanto al tiempo de cómputo, el ACO requiere de mayor tiempo para encontrar soluciones respecto a lo requerido por el AG. Estos valores son de esperarse, debido a que se ha probado en otros estudios que el ACO induce mayores tiempos de computación que los algoritmos genéticos [4]. Sin embargo, los tiempos de cómputo obtenidos son viables en entornos de simulación y aplicables a futuros escenarios reales, requiriendo hasta 12.9 segundos para sugerir una ruta de picking.

6 Conclusiones

Este artículo propone un ACO para minimizar la distancia recorrida en almacenes 2D multibloque, considerando una formulación de distancias mínimas entre cada par de posiciones de almacenamiento para solucionar el problema del ruteo del picking (PRP) como un Steiner TSP. A través de experimentos de simulación se ajustaron los parámetros más relevantes del ACO, y se demostró que el ACO presenta mejor desempeño respecto al AG, S-shape, y Aisle-by-Aisle, por lo cual, el algoritmo propuesto puede mejorar el desempeño de las operaciones de picking en almacenes y centros de distribución, brindando soluciones satisfactorias para la distancia recorrida en tiempo de cómputo viables para entornos operativos.

A decision support tool for the location routing problem during the COVID-19 outbreak in Colombia

Andrés Martínez-Reyes[1], Carlos L. Quintero-Araújo[1], and Elyn L. Solano-Charris[1]

Operations & Supply Chain Management Research Group, International School of Economic and Administrative Sciences, Universidad de La Sabana, Chía, Colombia

Abstract. During the outbreak of coronavirus disease 2019 (COVID-19) in Bogotá, Colombia, some strategies for dealing with the increasing number of infected people and the level of occupation of intensive care units include the use of Personal Protective Equipment (PPE). PPE is a crucial component for patient care and a priority for protecting health-care workers. For attending this necessity, the location of distribution centers within the city and the corresponding routes to supply the intensive care units (ICU) with PPE have an important role. Formally, this problem is defined as the Location Routing Problem (LRP). The LRP is an NP-Hard problem that combines the Facility Location Problem (FLP) and the Vehicle Routing Problem with Multiple Depots (MD-VRP). This work presents a decision support tool based on a simheuristic method that hybridize an Iterated Local Search (ILS) algorithm with Monte Carlo simulation to deal with the LRP with uncertain demands. Realistic data from Bogotá (Colombia) was retrieved using Google Maps to characterize the geographical distribution of both potential facilities and ICUs, while demands were generated using the uniform probability distribution. Our preliminary results suggest the competitiveness of the algorithm in both the deterministic and the stochastic versions of the LRP.

1 INTRODUCTION

In December 2019, a new coronavirus disease emerged characterized as a viral infection with a high level of transmission in Wuhan, China. Coronavirus 19 (COVID-19) is caused by the virus known as Severe Acute Respiratory Syndrome coronavirus 2 (SARS- CoV-2) established by the Coronaviridae Study Group of the International Committee on Taxonomy of Viruses (ICTV) [1]. As the cumulative numbers of confirmed cases have considerably increased worldwide, academics and practitioner are mainly concerned about modeling and prediction of COVID-19 ([2], [3]).

In Colombia, according to the report of August 4th, 2020, 33.9% of the cases are located in Bogotá D.C. (capital city) with 113,548 confirmed cases, and the 89.2% of the total intensive care units are occupied [4]. As COVID-19 is predominantly caused by contact or droplet transmission attributed to relatively large respiratory particles which are subject to gravitational forces and travel only approximately one meter from the patient [5], personal protective equipment (PPE) has become crucial for protecting healthcare workers and alleviating the burden in the hospitals and controlling the epidemic [6].

Considering the city needs and that most of the studies about COVID-19 deal with prediction models and do not integrate their results to support decision making, e.g., estimating cities' implications, supplies and demand of material resources; in this paper, we study the location of distribution centers within the city and the corresponding routes to supply PPE to the Intensive Care Units (ICU) and, therefore, support decision making. The problem is formally defined as the Location Routing Problem (LRP). The LRP involves all decision levels in supply chain management and logistics, i.e., strategic, tactical and operational. From an operations research perspective, it can be seen as the combination of two well-known NP-Hard problems such as the Facility Location Problem and the Vehicle Routing Problem with Multiple Depots. Thus, the LRP is also NP-Hard.

From a practical point of view, there is a recent trend to create both easy-to-implement and powerful algorithms when solving complex problems. Accordingly, in this work, we propose a simheuristic method based on an ILS algorithm in which initial solutions are created using a random choice of depots combined with a biased randomized version of the nearest neighbor heuristic. Readers are referred to [7] as a key literature review of simheuristics for dealing with stochastic combinatorial optimization problems. Moreover, with the aim of providing an easy-to-use tool, we have implemented our algorithm as an Excel Macro, considering its advantages in data manipulation, consolidation and analysis. Our preliminary results have been compared to the ones obtained by GAMS/Cplex for the deterministic LRP, showing promising results. Besides, we have carried out a set of experiments for the LRP with Stochastic Demands by combining our Iterated Local Search (ILS) algorithm with Monte Carlo simulation (MCS). The results on the stochastic version demonstrate that using safety stocks as protective policies against uncertainty could improve not only expected costs but also the reliability of the obtained solutions.

The remainder of this paper is organized as follows: section 2 presents the literature review; section 3 introduces the description of the problem; section 4 outlines the proposed approach; in section 5 we analyze the obtained results; finally, section 6 presents some conclusions and further research perspectives.

2 LITERATURE REVIEW

This section presents a brief literature review focusing on location routing problems and also on logistics applications for pandemics such as the current one generated by Covid-19.

2.1 Location Routing Problems

The LRP was initially proposed by [8]. Due to its complexity, the first studies on the LRP proposed to tackle it by separating the two related subproblems, i.e., the facility location problem and the vehicle routing problem. However, it has been demonstrated that such approach leads to sub-optimal solutions [9]. This complex problem can be used to support decision-making processes in different fields of application such as city logistics, humanitarian logistics, horizontal cooperation, among others ([10], [10], [11]).

Considering its NP-Hard nature, heuristics and metaheuristics yield better results than classical optimization approaches, specially for large sized instances [12]. We refer to [13] for an overview on LRP problems. The deterministic version of the LRP has been widely studied while its stochastic counterpart has been scarcely analyzed. In the stochastic demands version, the main assumption is that demands are not known in advance, i.e., the real value of demands is revealed once the vehicle arrives at the customer. Thus, routes failures will occurs whenever the aggregated demand in a route exceeds the vehicle capacity [14].

Among recent works on the LRP with stochastic demands (LRPSD), Quintero et al. [14] proposed a simheuristic algorithm to deal with the LRPSD. The authors proposed three simulation processes to deal with: (i) the estimation of the right safety stock policy to protect against uncertainty, (ii) estimate stochastic costs and reliabilities of the proposed solution, (iii) refinement of the estimation of both stochastic costs and reliabilities. However, their work was tested using benchmark instances adapted from literature, while in this work we use realistic data from Bogotá, Colombia related to the current pandemic.

2.2 Logistic approaches for dealing with COVID-19

Mainly, most of the literature on COVID-19 is focused on prediction models (e.g., [2], [3], [15]). Torrealba-Rodriguez et al. [2] studied the prediction of cases of COVID-19 infection in Mexico. Shen [15] considered the logistic growth modelling of COVID-19 proliferation in China and its international implications. Wang et al. [3] predicted the global trend and the specific trends of Brazil, Russia, India, Peru and Indonesia.

However, just few works integrate the results of the prediction models to support decision making. For example, Loske [16] analyzed the impact of COVID-19 on transport volume in German food retail logistics, as well as its resulting implications. The author proposed a regression analysis to validate the interdependencies of COVID-19 and transport logistics in retail logistics, and considered the reallocation of health care capacity, repurposing of hospitals, and close collaboration between the government and the health care committee. Zhang et al. [17] deal with the scheduling of vehicles to transport infected people to isolated medical areas and solved it using a metaheuristic approach. Yu et al. [18] propose the design of a multi-objective reverse logistic network in epidemic outbreaks. More specifically, this work aims to determine the location of temporary facilities

and transportation of the increased medical waste generated by a pandemic. Kaplan [19] combines predictive and prescriptive models for Covid related decision making such as crowd-size restrictions, hospital surge planning, timing decisions (when to stop and possibly restart university activities), and scenario analyses to assess the impacts of alternative interventions, among other problems.

To the best of our knowledge there are no published works on the location of depots and the consequent routing of PPEs (maks, gloves and disposable suits) for caregivers (physicians, nurses, therapyst, etc) located all long the city. Thus, the importance and novelty of this work.

3 PROBLEM DESCRIPTION

Due to the COVID-19 pandemic and its associated effects, many governments have adopted lock-down mechanisms as a strategy to diminish the speed of contagion and have more prepared health systems, especially by having a higher number of available ICUs. Particularly, in Bogotá - Colombia, lock-down started in March 2020 but currently, we are facing a high number of new cases and deaths every day. Besides, the occupancy of ICUs is becoming critical with a 90% value. Thus, logistic approaches are a must to optimize the response of the system to the current pandemic.

In particular, we aim to analyze the efficient delivery of PPE (composed by masks, gloves, and disposable suits) required by medical teams (physicians, nurses, and therapists) to take care of COVID-19 patients. In this work, we propose to study the location of distribution centers within the city and the corresponding routes to supply the different ICUs that are habilitated to receive COVID-19 patients in Bogotá. This situation could be represented by the Location Routing Problem with Stochastic Demands (LRPSD) due to the nature of the field of application.

The LRP considered in this work is adapted from [20]. As stated by [21], the LRP belongs to the class of NP-hard problems, which means that it is not possible to find optimal solutions for large-sized instances in reasonable computing times. The LRP is defined in a directed graph $G = (V, A, C)$. V is a set of nodes comprising a subset I of m possible depot locations and a subset $J = V \backslash I$ of n customers. The cost of any arc $a = (i, j)$ in the arc set A is given by C_a. A capacity W_i and an opening cost O_i are associated with each depot site $i \in I$. Each customer $j \in J$ has a demand d_j. A set K of identical vehicles of capacity Q is available. When used, each vehicle incurs a fixed cost F and performs one single route. The following constraints must be taken into account:

- Each demand d_j must be served by one single vehicle.
- All nodes are allocated to an open depot.
- The number of depots within the set must guarantee that total demand can be serviced.
- Each route must begin and end at the same depot and its total load must not exceed vehicle capacity.

– The total load of the routes assigned to a depot must respect the capacity of the selected depot.

The goal of our problem is to determine the subset of distribution centers (DCs) to open, allocate ICUs to DCs, and planning the routes from DCs to serve ICUs, in order to minimize the total expected costs. The total expected costs of a solution include the fixed cost of opening facilities F, the costs of traversed arcs, the fixed cost of using vehicles and the cost of recursive actions (in case of route failures due to the stochastic demands). The mathematical model of the stochastic version can be found in [14].

Figure 1 depicts a complete solution for our LRP. Potential distribution centers locations are represented by squares while ICUs are represented by circles. This figure illustrates how, from an initial problem setting (top-left), a complete solution could be obtained by *(i)* selecting the distribution centers to be opened (top-right), *(ii)* assigning ICUs to open DCs (bottom-left) and, *(iii)* creating routes from each DC to its allocated ICUs (bottom-right), while satisfying all constraints.

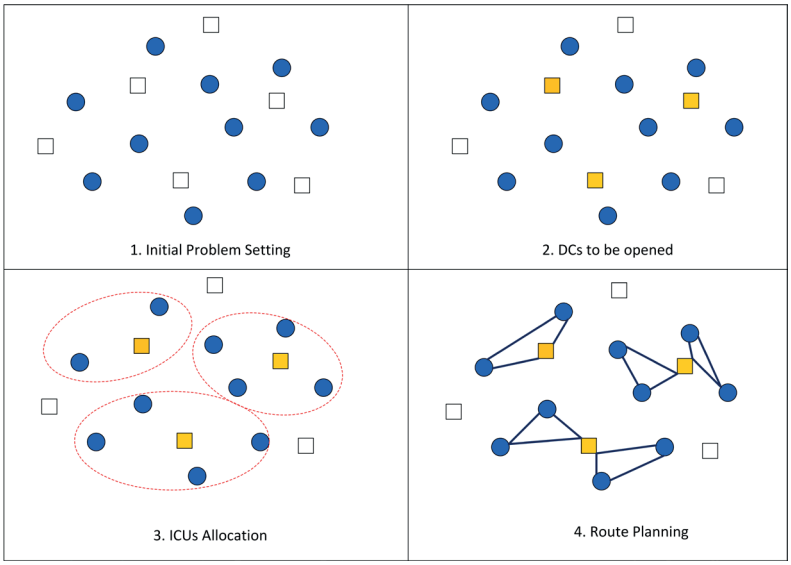

Fig. 1. A Complete Solution for our LRP

4 SOLVING APPROACH

To deal with the LRPSD, we have developed a simheuristic algorithm hybridizing an Iterated Local Search (ILS) algorithm [22] with Monte Carlo simulation. The

procedure is driven by the ILS while the simulation is used to test the quality of the solution in the stochastic setting of the problem. Considering that ILS is a powerful local search-based metaheuristic to deal with deterministic problems, we need to use a kind of protection policy (safety stocks) to face uncertainty and get better results in the stochastic setting of the problem.

Safety stock is used when planing routes to reduce the possibility of not serving some ICUs, when executing the planned routes, due to demand uncertainty. However, after a certain value (too conservative) of safety stock, expected costs tend to increase due to excessive deterministic costs. The idea, then, is to find the most convenient safety stock policy providing the best trade-off among costs and reliability.

Our proposed method is composed of three main phases: *(i)* location phase, *(ii)* customer allocation and, *(iii)* vehicle routing. To deal with the location decisions, we randomly open depots until the total available capacity is enough to serve total demands. Then, in the allocation phase, ICUs are randomly selected and assigned to the nearest open depot with the available capacity to serve it. Besides, the available capacity of the corresponding depot is updated and the ICU is marked as assigned. This process is repeated until all nodes have been allocated to an open depot. In case that a given ICU can not be assigned to any open depot due to capacity constraints, a new depot is opened and the customer is allocated to it. Here, solution failure due to depot capacity it is not considered. In the routing phase, the starting node for each route is randomly selected. Next, a modified version of the nearest neighbor heuristic is applied. A route finishes when the next customer to be added to the route can not be served due to vehicle capacity constraints, so the vehicle is sent back to the depot.

This three-phase process is executed during a given number of iterations and we keep the best solution found among them. The aforementioned solution is sent to a short simulation process to estimate stochastic costs and reliabilities. Stochastic costs are generated when a planned route can not serve a certain ICU and, as a consequence, a corrective round-trip from such ICU to the depot is executed to re-load the vehicle and resume the planned route. After the short simulation, the ILS framework is executed. To do so, we propose as a perturbation operator the interchange of an open depot with a closed depot, i.e., a previously open depot is closed and a previously closed depot is opened. The ICU is assigned to the closing depot are allocated to the opening one. A graphical representation of this operator can be seen in Figure 2. Moreover, two local search operators have been designed. The first one is the exchange of two customers among different routes from the same depot [23](see Figure 3 top) while the second one is the exchange of two customers from routes belonging to different depots (see Figure 3 bottom).

Promising solutions obtained by the ILS framework are passed through the short simulation process. Next they are stored in a pool of solutions which is sorted by increasing costs. Finally, the top-10 solutions stored within the pool are passed through a more intensive simulation process to refine both stochastic costs and reliabilities. The process is depicted in Figure 4.

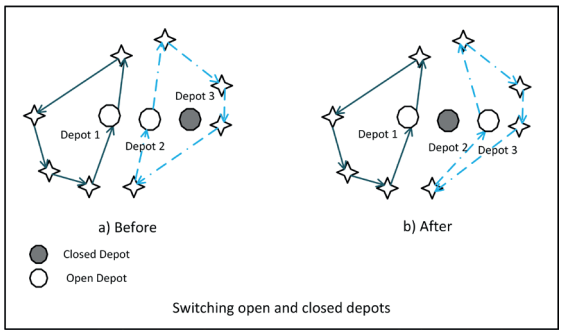

Fig. 2. Diversification Operator

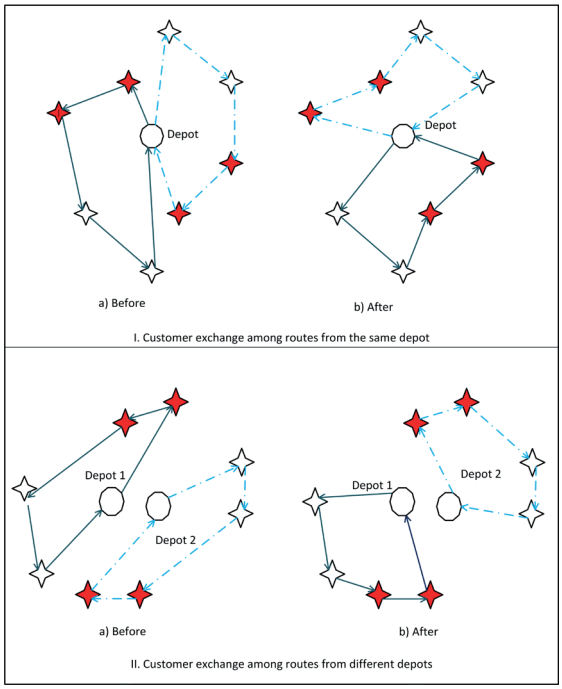

Fig. 3. Local-Search Operators

The reliability $reliab_r$ for each route r in solution S is computed as follows:

$$reliab_r = (1 - \frac{\sum_{n=0}^{TotalSimulationRuns} RouteFailures}{TotalSimulationRuns}) * 100\% \quad (1)$$

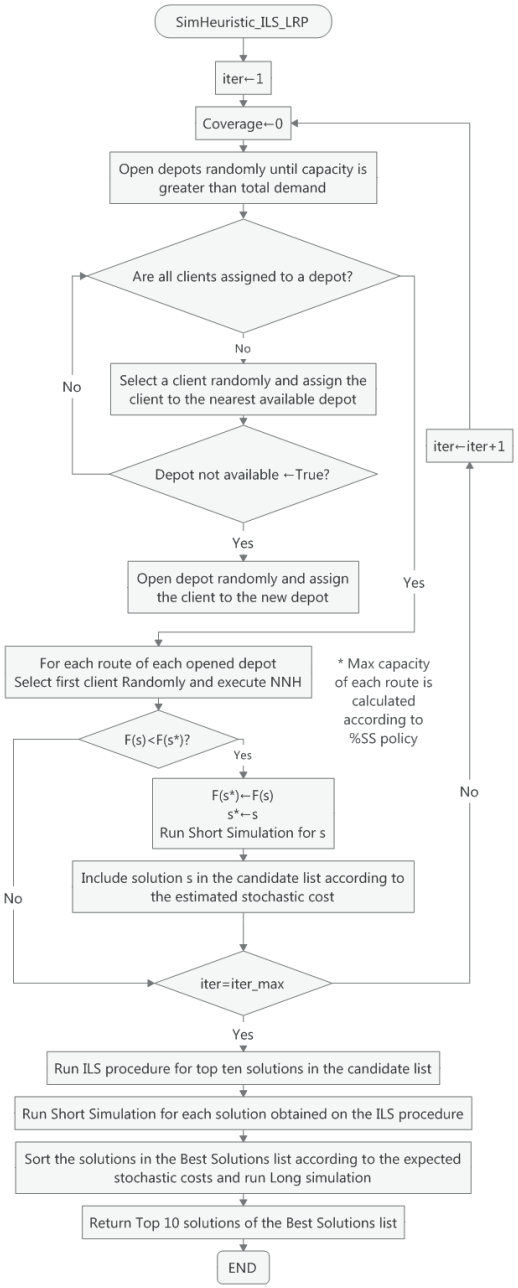

Fig. 4. Flowchart of the proposed method for the LRPSD

It is important to note that each route within a solution could be seen as an independent component of a series system, i.e., the proposed solution will fail if, and only if, a failure occurs in any of its routes ($RouteFailures$). Therefore, the reliability index of a solution S with R routes can be calculated as $\prod_{r=1}^{R} reliab_R$.

5 RESULTS AND ANALYSIS

The proposed algorithm was coded as an Excel macro using the Visual Basic for Applications (VBA) language. The version used for the spreadsheet was MS Excel 2013. As stated by [24], using spreadsheet-based solutions have several advantages such as interface familiarity, ease of use, flexibility, and accessibility. Moreover, since MS Excel is largely known around the world, using it as the engine for the spreadsheet provides additional benefits, such as integration with software packages that offer built-in functionalities to obtain/send data from/to MS Excel, and the possibility of customizing code in Visual Basic for Applications ([24]). It is also important to mention that using spreadsheet-based solutions may result in low-cost solutions that may yield significant savings for enterprises, especially in non-developed countries.

We have tested our proposed method using different instances with real locations in Colombia. Instances were generated by retrieving -from Google Maps- latitude and longitude coordinates belonging to retailing and warehousing points located in Bogotá (Colombia's main city and its capital). The expected value for demands corresponds to the PPE required for each ICU assuming that each patient is served by a team consisting of one physician, one nurse, and one therapist. The team visits each patient once per hour, so 24 visits are required during a complete day. The capacity of DCs was generated to guarantee the satisfaction of total demands. Opening costs, in US Dollars, for each facility corresponds to real construction costs of warehouses in Bogotá. The vehicle capacity corresponds to the real-load capacity of the Renault Kangoo, which is a vehicle broadly used in Colombia to execute urban distribution tasks. Instances considers 53 ICUs, 10 distribution centers, the distance matrix and variations on demands. The instances are named MQS-BOG#, where # identifies the number of the instance. All instances are available in https://cutt.ly/SpreadsheetSimheuristicILS.

All deterministic instances were modeled using the GAMS modeling language. However, due to the complexity of the problem, the Cplex solver was unable to find a solution after eight hours of execution time. Thus, we generate a set of reduced instances to have a fair comparison between the exact method and our proposed algorithm. To generate the reduced instances, we run our heuristic method and we get two open depots and their allocated customers from our best reported solution. Additional depots were randomly selected while ensuring the capacity to serve all ICU demand. All reduced instances are available in https://cutt.ly/ReducedInstances. The experiments were carried out using a standard windows PC with Intel® Core™ i7 – 6th generation and 8Gb RAM. Each instance was solved using five different random seeds. The obtained re-

sults are summarized in Table 1. GAMS/Cplex column shows the best solution reported by this software for each instance after 27,000 secs of computational time. It is worth mentioning that none of the solutions was proven as optimal. OBDS is the best deterministic solution reported by our algorithm among all executions, while OADS is the average value of the obtained solutions. Besides, GAP shows the percentual gap of OADS concerning GAMS/Cplex. We can see that, on average, our algorithm has an average gap of 1.64% compared to the results provided by GAMS/Cplex.

Table 1. Results - Deterministic Case

INSTANCES	SUB-PROBLEM	GAMS/cplex(1)	OBDS(2)	GAP% (2)-(1)

AVERAGE				1.64041%

As this work concerns the stochastic version of the LRP, we have transformed the deterministic instances by assuming their demands as the expected value (EV) of the stochastic case. Besides, stochastic demands are revealed once the vehicle arrives at the UCIs by using the uniform probability distribution $\sim U[EV - 10\%, EV + 10\%]$. It is worth to mention that any other probability distribution according to the real demand's behavior could be used.

Our proposed method was tested using five different random seeds and different safety stock policies as a security buffer to handle demand uncertainty i.e., 0%, 1%, 3%, 5% and 7%. The results are presented in Table 2. The setup time for the simheuristic was 7 minutes without including the simulation time. For each safety stock policy, the best stochastic solution (OBSS), the average of our top 10 stochastic solutions (OASS-10), the expected reliability of the OBSS (Reliab.), and the Gap among OBSS and OASS-10 are reported. It is worth to mention that the top 10 solutions for each of the instances tested with each safety stock policy show the same location decisions, clients allocation are similar and the major differences among them are due to the configuration of each route. Furthermore, Figure 5 shows the behavior of expected stochastic costs and reliabilities for a given instance when using different safety stock policies. As expected, when no protection is considered there are many route failures due to demand uncertainty. Therefore, we can see higher costs and lower reliability. On the other hand, when the value of safety stock policy increases, costs tend to decrease while reliability increases; however, when the safety stock is greater than 5%, costs start to increase again. Similar situation occurs for the different instances, i.e., costs start to decrease when the percentage of safety stock is increased and, at a certain point (ideal safety stock policy), the costs

reach its minimum value. After that value, costs become higher. This situation occurs when decision-makers for protecting against uncertainty, tend to greatly increase the % of safety stock for augmenting reliability and, therefore, costs are increased due to a higher number of planned routes.

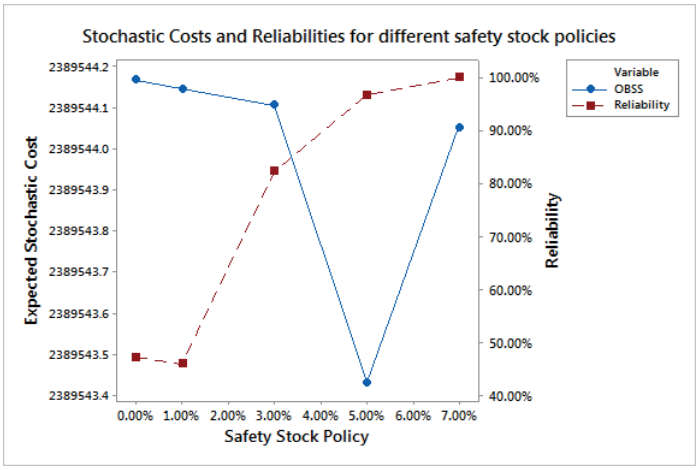

Fig. 5. Average Values of Expected Costs and Reliabilities of Our Best Stochastic Solutions for Different Safety Stock Policies

Moreover, in Figure 6 we present the Best Deterministic Solution (OBDS) for a given instance against the two best performing stochastic solutions with a safety stock policy of 5%. Besides generating lower expected stochastic costs, the stochastic solutions, even if they are not the optimal ones, show less variability than the deterministic one in the stochastic case.

6 CONCLUSIONS

This article has presented a decision support tool based in a hybrid method consisting of an Iterated Local Search algorithm combined with Monte Carlo simulation to deal with the Location Routing Problem with stochastic demands. This version finds applications in humanitarian logistics and last-mile deliveries problems. Our proposed method was tested using five different instances generated with Google Maps to characterise the geographical distribution of customers. Besides, different safety stock policies are tested.

Results show the behavior of the expected stochastic costs and reliabilities when using different safety stock policies per each tested scenario. Furthermore, results also show that this version of the LRP is a hard problem and its complexity increases according to the level of uncertainty. As expected, when no

protection is considered there are many route failures due to demand uncertainty and higher costs and lower reliability are obtained. On the other hand, when the value of safety stock policy reach the ideal value, costs tend to decrease while reliability increases.

Regarding future research, there is a room for including other representations for uncertainties and to design other approaches for handling them. Moreover, adaptation for large scale problems will be also considered.

Abstract. This article presents a metaheuristic approach applying simulated annealing for the problem of planning corridors for oil pipelines facilities. The corridor location problem requires finding an optimal or a set of sub-optimal alternative routes between two locations, accounting for cost optimization and topographical constraints. The proposed simulated annealing applies a path-based search for exploring the space of possible routes. The experimental evaluation solves realistic problem instances considering real information of Veracruz, Mexico. The proposed approach is able to compute a set of near-optimal alternative routes that improve up to 34.1% of the terrain impact cost over a greedy pathfinding reference method, such as the ones included in traditional geographical information systems.

Keywords: Corridor location, simulated annealing, path analysis, shortest path optimization

1 Introduction

The right-of-way (ROW) or *corridor* is a crucial requirement for the construction of linear installations such as pipelines, electric transmission lines, roads, among others [19]. The planning process of real corridors must consider legal, social, political, environmental, engineering, and economic factors, which make the design process complex [17]. Proper planning of ROW explores different paths based on design specifications, environmental laws, and good practices to determine the best option, which is the goal of the corridor location planning [4].

The corridor location problem (CLP) can be modeled as an optimization problem, subject to topographic constraints such as distance, obstacles, environmental impact, and safety [19]. Locating a corridor is analogous to identifying the shortest or least-cost path for the facility to be designed on a landscape [26]. Traditional approaches to solve the corridor location problem are based on generating a set of alternate routes through enumerative methods [24], using penalty techniques [14], or by specifying one or multiple intermediate points where the route must pass [22] depending on the size of the area across the landscape where the corridor could pass [8]. The problem of generating alternate routes has led

researchers to develop solution methods that use different types of representation of the domain, through graphs; they use deterministic shortest path methods, such as Dijkstra and its variants to get only one path at a time (optimal route). However, the Dijkstra algorithm and its variants are costly, since the computing time to find the shortest path using exact methods increase based on the network size. For this reason, additional mechanisms generating more than one route at a time are useful contribution in this area.

Geographical Information Systems (GIS) facilitate the management of geographic information using raster (2D grid of measurable numerical characteristics of the projected area) and vector (representation of the projected area through points, lines, and polygons) data models. The efficient handling of the data models affects map analysis speed. Distance measurement permits identifying the optimal path by an accumulated surface cost raster layer (ASC) performed on spatial analysis [7],[2]. ASC raster layer represents a weighted graph associating a value (weight) on every edge on an appropriate scale that corresponds to the goals and objectives for every raster cell involved in the corridor design. Generally, GIS tools use the Dijkstra algorithm and its variants for the spatial analysis, without considering the generation of alternate routes [10]. Unlike exact techniques, metaheuristics cannot guarantee to obtain the optimal solution to a problem. However, metaheuristic techniques are more efficient than exact techniques in solving complex optimization problems [20]. Simulated Annealing (SA) is a metaheuristic method that finds reasonable solutions for combinatorial problems over large solution spaces [12]. SA implements a local search guided through a stochastic process with a given probability. The quality solution can be improved using a neighborhood search in the SA algorithm. The neighborhood structure allows searching for approximate solutions, adjusted to the complexity and nature of the problem [6].

In this line of work, this article presents a SA metaheuristic approach for the CLP. The space exploration allows computing different alternatives routes between origin and destination points, generating competitive and spatially different routes alignments. Realistic problem instances are solved in the experimental evaluation, using real information of the Veracruz state, a well-know oil production area in Mexico. Accurate results are reported: the proposed SA allows computing a spatially diverse set of near-optimal alternatives that improves up to 31.4% the results of traditional methods included in GIS software.

The rest of the article is structured as follows. Section 2 describes the corridor location problem and the optimization model of the shortest route. Section 3 describes the proposed SA metaheuristic approach, including the method for generating the initial solution. Section 4 provides details of the experimental evaluation of the proposed approach, including the description of the real scenarios and the discussion of the results. Additionally, the corridor paths obtained by the proposed SA are displayed on GIS software. Finally, Section 5 presents the conclusions and formulate the main lines for future work.

2 The corridor location problem

This section describes the corridor location problem, presents its mathematical formulation, and reviews related works about traditional approaches to solve the problem based on enumerative methods, penalty techniques, and by specifying intermediate points where the path must pass.

2.1 Problem description

In the construction of linear facilities such as pipelines, communication networks, transmission lines, etc., it is essential to permit access to public land that will house the facilities. Therefore, one of the factors to consider is the use of existing or new ROWs [19],[15]. Specific laws demand considering alternative routes in a ROW project to determine the optimal route for the corridor across public and private terrains. In the context of line-based facilities, two important concepts are distinguished, depending on the location perspective: in a path, the facility is placed on an existing network composed of street/road segments and intersections; instead, a corridor is open in terms of being a route that lies anywhere on the landscape [5]. The linear facility design process is split into two stages. In the first stage, the best compromise route is determined, based on the objectives of the interested parties. In the second stage, the engineering and construction design and the facility accessories must be included in the design process [17]

This work focuses on the first stage of the facility design process. The goal is to generate alternative routes, to be analyzed in a posterior decision-making process to determine a proper route for corridor location. Relevant attributes are considered for route generation, including a cost function that considers topographical information and the height of the candidate locations for the route.

2.2 Mathematical Formulation

The CLP is formulated as the problem of finding the shortest path between source and destination in an undirected weighted graph $G = (N, A, h, c)$ [26].

The graph G represents a Cartesian grid used to discretize the area where the corridor is to be built. $N = \{u_1, u_2, ..., u_n\}$ is the set of graph nodes. Each node represents the center of a cell in the rectangular grid specified by a point (x, y, z), where z is a non-negative integer value based on the digital elevation model (DEM), and x, y are in terms of latitude and longitude coordinates from the Universal Transversal Mercator (UTM) reference system. Each grid cell is linked to its eight neighboring cells. $A = \{(u_{i1}, u_{j1}), (u_{i2}, u_{j2}), ..., (u_{im}, u_{jm}\}, u_{ik}, u_{jk} \in N$ is the set of edges; $n = |N|$ and $m = |A|$. An edge $(u_i, u_j) \in A$ connects nodes u_i, and u_j. Function $h : N \to \mathbb{Z}^+$ assigns a non-negative height (the *elevation*) to each node. In turn, function $c : A \to \mathbb{R}^+$ defined by Eq. 1, assigns a non-negative cost to each edge $(u_i, u_j) \in A$.

$$c(u_i, u_j) = \frac{\sum_{k}^{|L|} L^k(i, j)}{|L|} \tag{1}$$

In Eq. 1, $L^k : \{1, ..., n\} \times \{1, ..., n\} \rightarrow \mathbb{R}$ is the k-th *topographic layer* considered for the area where the corridor is to be built. Each topographic layer represents specific information about roads, buildings, land use, and other relevant features about the terrain, and values for each cell (i, j) are classified on a zero to ten scale, according to a passing penalty between node u_i and node u_j. Higher passing penalty are associated to higher costs.

The problem proposes finding the minimum-cost path from a given source node s to a destination node t. The objective function to minimize (Eq. 2a) represents the total viability cost of edges chosen for the path. In the proposed formulation, each edge (u_i, u_j) has associated a binary decision variable x_{ij} that is equal to 1 if the edge is included in the optimal shortest path and 0 otherwise.

$$\min f(x) \quad = \sum_{(u_i,u_j)\in A} c(u_i, u_j) \cdot x_{ij} \tag{2a}$$

subject to

$$\sum_{(u_i,u_j)\in A} x_{ij} - \sum_{(u_j,u_i)\in A} x_{vu} = \begin{cases} 1 \text{ if } u_i = s \\ -1 \text{ if } u_i = t, \\ 0 \text{ if } u_i \neq s, t. \end{cases} \tag{2b}$$

$$x_{ij} \in \{0, 1\} \quad \forall (u_i, u_j) \in A \tag{2c}$$

$$h(u_i) \leq DEM_{max} \tag{2d}$$

Eq. 2b express the flow conservation constraint, ensuring that the computed path starts on the origin node $s \in N$ and ends on the destination node $t \in N$. Eq. 2c is the integrity constraint for the binary decision variable x_{ij}. Finally, Eq. 2d is the elevation penalty constraint, which states that node u_i avoid steep slopes in the path through an established maximum height (DEM_{max}) for the corridor route location.

2.3 Related work

The iterative penalty method assigns penalty parameters to the edges of the graph once one of them has been selected to be part of a solution. The efficiency of the algorithm depends on the penalty strategy implemented. Regardless of the penalty strategy, many alternatives generated are parallel lines to each other. The method was initially proposed for road design [24] and used for routing hazardous materials delivery [11], among other applications. Lombard and Church [14] introduced the Gateway Shortest Path method (GPS), based on a shorter route problem with restrictions. It generates a short route called "Gateway Shortest Path" between a source and a destination, restricted to pass through a specific node (the *gateway*). The method allows identifying different acceptable alternate routes, with less computational effort than the iterative penalty method.

A different approach for generating alternate routes is the k^{th}-shorter routes (KSR) method [25], which generates a classified list of the k lowest cost routes. After generating the first route, KSR excludes one edge from the network included in the solution; the network is modified iteratively to generate different alternatives. A similar method is Near-Shortest Path (NSP) [3], which generates k routes within a specific costs range, without classifying them.

Other proposed methods for generating alternate routes for corridors are Minimax [13] and p-dispersion [1]. The Minimax method is a greedy approach that begins by generating the shortest k routes between an origin and a destination, to build a subset of different routes. The p-dispersion method generates a broad set of candidate routes and selects a subset of p routes using a dispersion model that maximizes the minimum difference between any pair of selected routes. In contrast, Scaparra and Church [22] extended the GPS method by considering multiple gateway points to generate more complex paths, but with a higher computational cost.

Other approaches make use of parallel computing to run parallel methods such as KSR and NSP [16]. Exact algorithms guarantee to find the optimal global solution; however, in the worst case, the computation times can be exponential depending on the size of the problem [9]. The computation time and effort scale to the extent that solving the problem is intractable for realistic problem instances [8]. An alternative solution to deal with this type of problem is through non-deterministic heuristics, capable of generating optimal solutions in reasonable computation time. Zhang and Armstrong [26] proposed Multi-Objective Genetic Algorithm for the Corridor Selection Problem (MOGADOR), which generates a wide set of Pareto optimal and near-optimal solutions. The objective functions that it minimizes calculate the suitability of the accumulated corridor aligned to engineering costs, environmental cost, and socioeconomic cost. Experimental results showed that MOGADOR, through the designed and implementation of specific genetic operators for corridor alternatives outperforms conventional approaches based on shortest path algorithms, both in terms of computational complexity and the quality of generated route alternatives, contributing to GIScience-based spatial analysis.

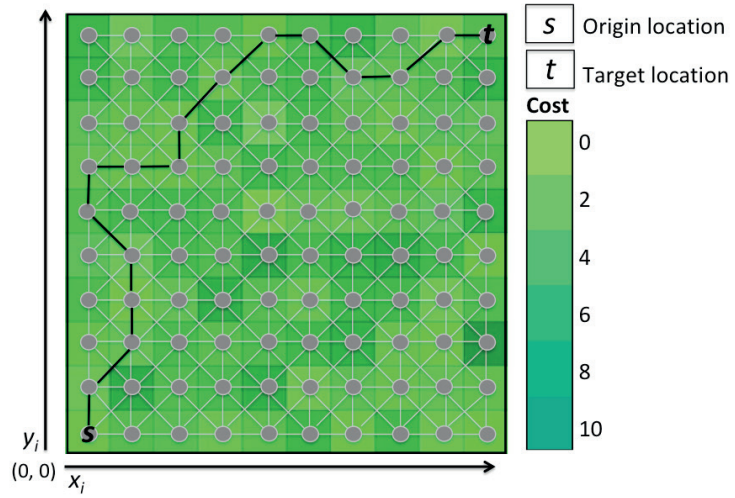
3 The proposed SA for the CLP

This section describes the proposed SA metaheuristic approach to solve the CLP.

3.1 Simulated Annealing method

Simulated annealing is a stochastic search algorithm based on a heat treatment process by altering the structure of a solid in order to change its properties [12]. The annealing process requires heating and then slowly cooling the solid to obtain a robust structure [23]. In the annealing process, the free energy of the solid minimized; that is, the atoms of the solid moves freely (i.e., randomly) on high temperatures, and then the atoms are rearranged themselves through lower

temperatures, producing a minimum energy state of the system. The cooling schedule permits gradually to decrease the temperature until it reached an equilibrium state. However, if the solid is cooled too quickly or the initial temperature of the annealing is too low, a higher energy state would reach arriving into an amorphous state. An analogy is formulated between the annealing of solids and an optimization problem to solve. The system state corresponds to a solution of the optimization problem; the free energy of the system is analogous to the objective function cost of the problem to be optimized; the slight system state change (perturb the system state) is analogous to a local search of solutions into a solution neighborhood (correspond to the mutation operator used on Evolutionary Algorithms); the cooling schedule corresponds to the control mechanism of the parameters (initial temperature, equilibrium state, cooling function, stopping criteria or final temperature) in SA algorithm; the final system state (frozen state) corresponds to the final solution by the SA algorithm (global optimum).



SA consists of empowering an iterated local search method through a procedure that allows accepting lower quality solutions than the current solution to escape from local optimum. In this way, SA explores and exploits the search space to find better solutions [20]. The SA process begins with high temperatures where random changes are accepted, altering the initial state continuously, with a slight decrease in temperature. In this way, the number of accepted changes decreases until none change is accepted. Finally, the process converges and stops with a profoundly modified initial state. SA is an iterative local search guided through a stochastic process, where a j state is accepted with a determined probability given by $\Pi(\Delta E, T) = exp^{-\Delta E/kT}$, where k is the Boltzmann constant. The Metropolis algorithm [18] simulates the change of energy in the cooling process of a physical system. SA works over a representation of candidate solutions, defined according to the specific features of the problem to solve.

The iterative method requires an initial solution, which is generated by applying a random initialization procedure or using a heuristic method incorporating knowledge of the problem. The exploration is performed changing the system state (candidate solution), which corresponds to generate local movements in the neighborhood of the current state. This state change is applied in order to increase diversity in the search. Once the state is slightly perturbed, if the energy change produced by the perturbation is negative, the new system state is accepted; otherwise, if it is positive, it is probabilistically accepted according to the Boltzmann distribution function. The starting temperature must be balanced between high and low values to conduct the local search in enough time to allow movements in the neighborhood. The initial temperature decreases gradually (cooling), if the decrease in temperature is slowly, better solutions obtained but with more significant computation time. The equilibrium state at each temperature must permit to apply sufficient movements proportional to the neighborhood size. Finally, the stopping criterion is related to the final temperature parameter, which is regularly a low value, near to zero.

3.2 SA for the CLP

The main features of the proposed SA algorithm for the CLP are described next.

Solution representation. A two-dimensional representation is used to encode candidate solutions for the CLP in the proposed SA. Two vectors of integer numbers ($\vec{x}$ and $\vec{y}$) are used to encode a path $p = \{u_0, u_1, \cdots, u_k\}$ between a source node s and a destination node t ($u_0 = s$, $u_k = t$). Value (x_i, y_i) in the representation correspond to the indexes of the i-th node in the path, in the Cartesian grid used to discretize the area where the corridor is to be built. Fig. 1 presents a sample representation for a CLP solution from origin $s = (0, 0)$ to destination $t = (9, 9)$ on a 10×10 grid discretizing a given terrain.

Y	0	1	2	3	4	5	6	6	6	7	8	9	8	8	9	9
X	0	0	1	1	1	0	0	1	2	2	3	5	6	7	8	9

Fig. 1: Sample representation for a CLP solution from origin $s = (0, 0)$ to destination $t = (9, 9)$ on a 10×10 terrain

Objective function. The proposed SA for CLP minimizes the cost function defined in the mathematical formulation (Eq. 2a).

Initial solution. The initial solution of SA for CLP is generated using an uninformed search, according to the pseudocode presented in Algorithm 1. Starting from the origin node, the neighboring node with the lower cost is selected in each iteration step, applying the Queen's movement (orthogonal plus diagonal), a standard method to reduce infeasible solutions in continuous terrain and increase cell connectivity that allows improving the accurate distance measurement by up to 30% over other movements [26].

Algorithm 1: Uninformed search for SA for CLP initialization

Data: $G(N, A, h, c)$, source node $s \in N$, target node $t \in N$
Result: Vector path $p = \{u_0, u_1, \cdots, u_k\}$

```
Create a queue q = ∅                                   ▷ queue of nodes
Create a vector p = ∅                                  ▷ path to return
q.push(s)
p.push(s)
Label s as visited
while ! q.empty() do
    u_i = q.pop()
    if u_i == t then
        return vector p                          ▷ destination node reached
    else
        for each adjacent node u_j of u_i
        if !visited(u_j) then
            Label u_j as visited
            q.push(u_j)
            p.push(u_j)                              ▷ include node in path
        end
    end
end
```

Algorithm 1 uses a queue structure q to store nodes of the graph. The process starts from the origin node s. This node is enqueued into q. Then, the process explores the adjacent neighbor node u_i before moving to the next level neighbors. If u_i is the destination t, the process finishes and returns vector p; otherwise, the procedure selects an adjacent node u_j of u_i and evaluates if has not been visited; in this case it is selected, marked as visited, queued into q and into the path vector p. Subsequently, u_j becomes the current node and the process of selecting its adjacent nodes is repeated until finding the destination node t.

Exploration. The exploration operator randomly selects two points of the current solution and explores alternate routes through prohibited and guided movements. Both random points must be different from the origin and destination, and different from each other. The random points are labeled as new starting point s_{new} (the nearest point to the origin s) and new destination point t_{new}. A pseudo-random path is created between s_{new} and t_{new}. Two criteria are considered to avoid infeasible solutions: if there is any common point between the current solution and the pseudo-random path, the solutions are merged in that point to create a new solution; otherwise, an A^* pathfinding algorithm is used to merge both paths and create a new feasible solution.

Annealing schedule. A geometric update scheme is applied for the temperature, i.e., $T^{k+1} = \alpha T^k$. The value of α is set by empirical analysis (see section 4).

Stopping criterion. A fixed effort stopping criterion is applied: SA-CLP stops when the temperature reaches a fixed minimum value (determined empirically).

Algorithm 2 presents a pseudocode of the proposed SA for the CLP. The main difference with a canonical SA method is the information stored during the search. SA is a memoryless search algorithm; i.e., it only use information from the last step of the search to compute a new solution. However, the CLP requires a set of efficient and spatially different route alternatives. Thus, up to n_S local optima solutions are stored in a vector P during the local search process.

Algorithm 2: Proposed SA for the CLP

```
k = 0
initialize(s_k)                                   ▷ generate initial solution
T_k = T_max                                       ▷ initialize temperature
P(n_S) ← ∅                                        ▷ initialize the vector of solutions
while T_k < T_f do
    i = 0                                         ▷ Markov chain iterator
    while i < maxL do
        s^{k+1} = perturbation(s^k)               ▷ exploration
        if f(s^{k+1}) < f(s^k) then
            s^k ← s^{k+1}                         ▷ acceptance criterion
        else
            Δf = f(s^{k+1}) − f(s^k)
            Π(Δf) = exp^{−(Δf/T_0)}
            β = random(0,1)
            if β ≤ Π(Δf) then
                s^k ← s^{k+1}                     ▷ accept sub-optimal solution
            end
        end
    end
    insert(P, s^k)                                ▷ store in solutions vector
    T_k ← αT_k                                    ▷ temperature decay
    i ← i + 1
end
return s^k
```

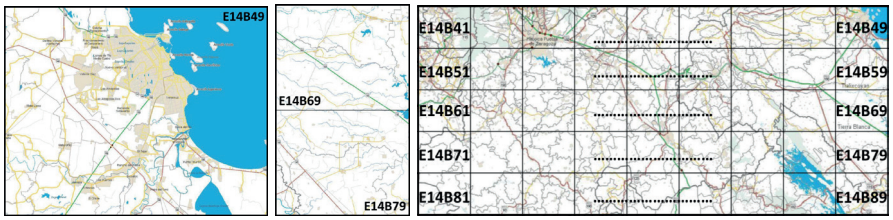
SA starts from the initial solution s^0 and proceeds to search for feasible solutions through an iterative local search in the neighborhood of size $N(s)$. At each iteration, a perturbed neighbor s^{k+1} is generated. Feasible perturbed solutions that improve the cost function (Eq. 2a) are always accepted. Perturbed solutions that do not improve cost are accepted according to a probability that depends on the current temperature T_k, and the Boltzmann probability function $\Pi(\Delta f)$). A maximum number of iterations (maxL) are performed to analyze different perturbed solutions in a Markovian search with the same value of the temperature parameter. The value of maxLenght is set by empirical analysis, accounting for the computational cost and the number of improved solutions in the Markovian search. The SA algorithm stops when the temperature reaches the final value T_f determined by empirical analysis (see section 4).

This way, the proposed metaheuristic approach determines the optimal route between two points across a geographic terrain for the CLP. Likewise, space exploration allows generating different alternatives routes between origin and destination points for competitive and spatially different route alignments in the corridor location. The next section analyzes the experimental results of the proposed approach.

4 Experimental results and discussion

This section describes the experimental evaluation of the proposed SA for the CLP. Details about the platform used for development and execution are presented. Likewise, the studied scenario and problem instances are described. Experimental results of the parameter calibration are reported. Finally, results for the addressed real-world problem instances are reported and discussed.

4.1 Development and execution platform



The proposed SA method was developed in C++11 and evaluated on a Quadcore Xeon E5430(2.66GHz), 8GB RAM, from National Supercomputing Center (Cluster-UY), Uruguay [21]. QGIS 3 was used for data visualization.

4.2 Studied area and problem instances

The studied area is located in Veracruz State, on the Gulf of México. Veracruz State has a territorial surface of 71 699 km^2. The Veracruz Basin is an essential depot of gas and petroleum with an area of 34 824 km^2, containing a potential number of oil extraction wells that distribute to other regions of Mexico.

Four problem instances were built using GIS data models of the studied area. Tested instances include remarkable spatial objects considered in a real-world pipeline facility construction. The assigned penalty impact cost to the spatial objects are: industrial facilities, airports, port lighthouse, runway aviation and bridges (10), electric substations, railways, port facilities, sports facilities and communication lines(9), water channel, water bodies, water ponds (human consumption), aqueducts, sand mining zones, cemeteries, urban areas and buildings (8), watershed, communication facilities (7), highways and rural locations (6), streets, racetracks, flood zones, rural paths and oil ducts/pipelines (5), green areas (not protected areas), sandy soils and growing areas (0). The DEM data model used has a raster BIL format, and each spatial object has a vector shapefile format. The UTM coordinates information of the spatial objects was converted from BIL raster to ASCII-TXT format using QGIS3, and from shapefile format to ASCII-TXT format using OGR/GDAL and Phyton 3. The methodology to build each problem instance considers creating an ASC raster through weighting the penalty impact costs of the spatial objects used from each topographic chart, using Eq. 1.

Problem instances #0 and #1 include the municipality of Veracruz (topographic chart E14B49); problem instance #2 includes the municipalities of Naranjos (E14B69) and Tierra Blanca (E14B79); and problem instance #3 includes part of the territories of Morelos, Puebla, and Veracruz states (E14B41-49, E14B51-59, E14B61-69, E14B71-79, and E14B81-89). Fig. 2 shows the topographic charts of the tested problem instances at map scale 1:50,000.

(a) #0 and #1 (b) #2 (c) #3

Fig. 2: Problem instances in the studied area, at map scale 1:50,000

4.3 Parameters configuration

The SA parameters must be adjusted to determine the configuration that allows computing the best results. Parameters tuning is made by an empirical sensitivity analysis performed over problem instance #0. The studied parameters and candidate values included: $T_0 \in \{2.0, 1.3, 0.9, 0.3, 0.1\}$, $T_f \in \{10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}\}$, $\alpha \in \{0.99, 0.98, 0.97, 0.96, 0.95\}$ and maxL $\in \{100, 50, 20, 10, 5\}$. Due to the stochastic quality of the simulated annealing, statistical analysis was applied to select the best configuration. 30 independent executions of SA were performed. Then, the Shapiro-Wilk test was applied to check normality. Results discarded the normality hypothesis with p-value $< 10^{-2}$. Thus, the Kruskal-Wallis (KW) non-parametric test was applied to analyze the differences between the results distributions. Table 1 reports the comparative analysis for each parameter value studied. The parameter values that allowed computing the best results on the tested instance (marked in bold in Table 1), with statistical significance according to the KW test were $T_0 = 2.0$ (KW p-value 0.017), $\alpha = 0.98$ (KW p-value 0.006), maxL $= 50$ (KW p-value 0.0016), and $T_f = 10^{-6}$ (KW p-value $> 10^{-2}$). Figure 3 graphically shows the behavior of the studied cooling schedule parameters values for the parameter setting instance.

4.4 Experimental results

A greedy strategy was implemented as a baseline for evaluating the results of the proposed SA-CLP. The greedy algorithm iteratively builds solutions taking local optimal decisions at each step (i.e., the adjacent node with the lowest cost is selected to be included in the path). When no feasible node is available to be selected, the method returns and chooses the second-best adjacent node. The procedure is repeated until reaching the destination node.

Table 1: Results of the sensitivity analysis of SA-CLP parameters

T_0	$f(s^k)$ worst	$f(s^k)$ best	$f(s^k)$ median	α	$f(s^k)$ worst	$f(s^k)$ best	$f(s^k)$ median
2.0	3024.40	2049.51	**2096.15**	0.99	2915.40	2046.41	2127.45
1.3	2915.40	2046.41	2127.45	0.98	2856.50	2046.40	**2073.05**
0.9	2566.40	2047.51	2133.80	0.97	3356.40	2057.30	2138.91

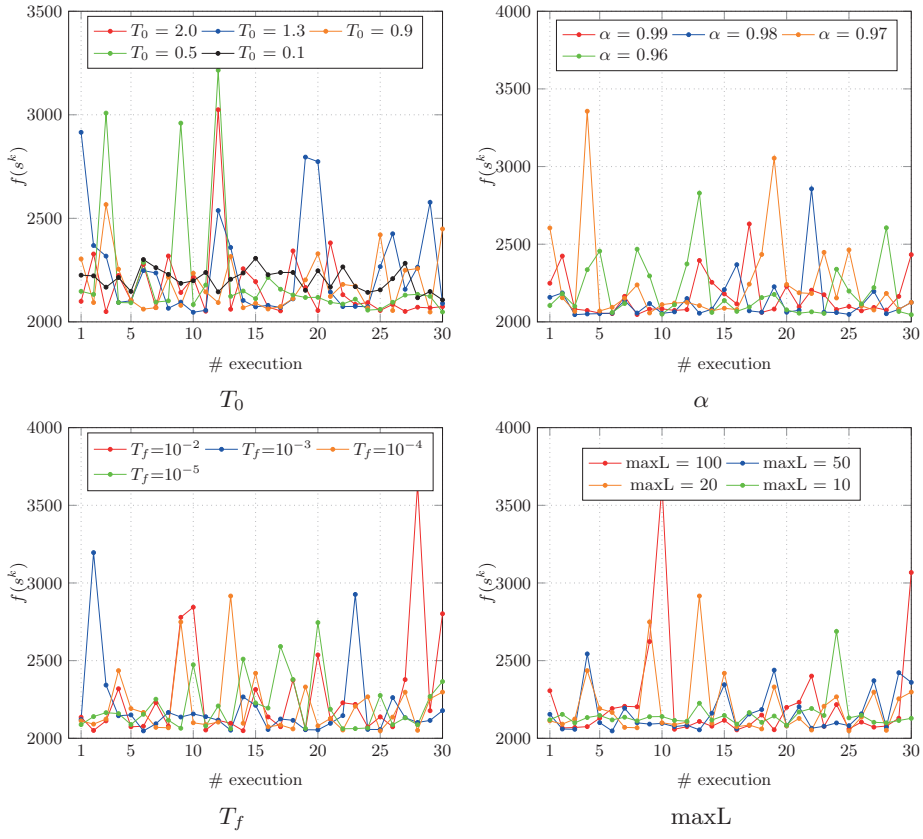

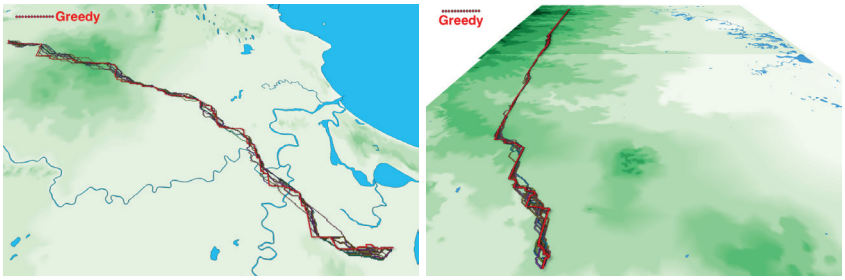

Fig. 3: Sample results of the sensitivity analysis for problem instance #0

Table 2 reports the median of the best objective function values ($\overline{f(SA)}$) computed by the SA-CLP and the comparison with the reference algorithm ($f(greedy)$). The relative improvement on objective function values (Δ_f) over the reference algorithm are also reported.

Table 2: Cost solutions for the studied problem instances

instance	size	origin, destination	$f(greedy)$	$f(SA)$	$\overline{f(SA)}$	Δ_f
#0	586×732	(44,365) (512,50)	3202.2	**2048.6**	2109.2	34.1%
#1	586×732	(292,551) (537,8)	2413.6	**1835.0**	2010.2	16.7%
#2	585×1467	(24,264) (113,1071)	9350.7	**7785.2**	8267.1	11.5%
#3	5341×6727	(221,47) (2525,6073)	63622.4	**55164.9**	57340.7	9.8%

Results in Table 2 indicate that the proposed SA-CLP is able to improve significantly over the greedy algorithm, regarding the cost function values. Considering the baseline results computed by the greedy algorithm, improvements of up to 34.1% were obtained in problem instance #0. Also, the solutions computed by the SA-CLP were between 9% and 16% better than the greedy algorithm in problem instances #1, #2, and #3. SA-CLP computed significantly competitive and slightly spatially different routes alignments on every problem instance. The SA-CLP execution with the parameter values reported in subsection 4.3 allows computing 492 different alternative routes between origin and destination points for the problem instances #0 and #1. For problem instances #2 and #3, SA-CLP computed 452 routes alignments each one. The competitive and spatially different route alignments for corridor location are displayed using a GIS tool. Figure 4 shows two samples of alternative routes for the corridor location in problem instances #1 and #2.

5 Conclusions and future work

This article presented a metaheuristic approach to solve the CLP, a relevant problem related to the construction of linear facilities such as pipelines, electric transmission lines, and roads. A SA metaheuristic was applied to generate different and competitive alternative routes between origin and destination points.

The proposed exploration pattern applies an uninformed search for initialization and a specific exploration operator that modifies randomly selected subsegments of the current solution. Alternate routes are explored through prohibited and guided movements, and the A* pathfinding algorithm is applied for merging. Furthermore, the standard memoryless search pattern in SA is extended to store a vector of local optima solutions to be considered as alternative routes.

The experimental evaluation focused on four realistic problem instances defined over real information of the Veracruz state, a well-know oil production area on the Gulf of Mexico. Parameters configuration was performed via a sensitivity analysis that studied four relevant SA parameters: initial and final temperature, the decay factor of the annealing schedule and the length of the Markov chain used for exploration. Statistical analysis were applied to study the results distribution by checking normality and determining the significance of the median values for each parameter configuration. Using the best configuration from the previous analysis, the proposed SA allowed computing a spatially diverse set of near-optimal alternative routes that improves up to 34.1% the results of a greedy algorithm, such as the ones included in traditional GIS software.

The main lines for future work are related to extend and improve the neighborhood search to address the reduction of improvements over the traditional greedy approach when solving large problem instances, e.g., by applying hybrid approaches combining exact and metaheuristic methods. The experimental evaluation of the proposed approach should also be extended to consider a larger number of synthetic and real scenarios. Multiobjective versions of the problem and multiobjective metaheuristics should be studied to compute and analyze distance and penalty impact cost simultaneously.

Resumen Este trabajo presenta un Multi-objective Evolutionary Algorithm (MOEA) el cual divide el espacio de los objetivos (OSD), en varias regiones utilizando la solución Nadir calculada ésta en cada generación del algoritmo. Para la clasificación de las soluciones de las distintas regiones en frentes no-dominados, se utilizan diferentes estrategias de optimización de las funciones objetivo. La idea es intensificar la diversidad del frente aproximado de soluciones no-dominadas alcanzado. El algoritmo propuesto (NSGA-II/OSD) se implementa sobre el algoritmo NSGA-II y se ensaya sobre el Problema de la Mochila Bi-objetivo (0-1 MOKP). Con baja dimensionalidad (2-3 objetivos), este problema es de difícil resolución para un MOEA dado el elevado número de soluciones superpuestas que se generan durante su evolución. El método propuesto ofrece muy buen desempeño cuando es comparado con los algoritmos NSGA-II y MOEA/D muy reconocidos ambos en la literatura especializada.

Palabras clave: Algoritmos evolutivos multi-objetivos , Optimización, Bi-objectivo Problema de la Mochila

1 Introducción

Un problema de optimización multiobjetivo (POM) es aquel que corresponde a una cierta realidad industrial, económica o de otra índole y sobre el que un decisor desea optimizar varios objetivos usualmente en conflicto entre sí. Cuando se resuelve un POM de complejidad difícil, métodos metaheurísticos son muy apropiados. Estos métodos no grantizan obtener el frente exacto de soluciones no-dominadas, pero sí un conjunto aproximado.

La segunda generación de algoritmos evolutivos multiobjetvo (MOEAs), ha demostrado obtener excelentes resultados resolviendo POM [1]. De naturaleza estocástica, los MOEAs están basados en el concepto de población de soluciones lo que les proporciona gran destreza para encontrar múltiples soluciones no-dominadas en espacios de soluciones de diversa naturaleza. NSGA-II [2] y MOEA/D [3] son entre otros [4], [5], [6], [7], dos MOEAs muy reconocidos en la comunidad científica multiobjetivo. El primero, utiliza una clasificación de rangos por dominancia como mecanismo de convergencia, mientras que crowding-distance es el mecanismo usado para diversificar las soluciones. El segundo, funciona descomponiendo el POM en un número de subproblemas escalares o mono-objetivos que son resueltos todos a la misma vez mediante la evolución de una población de soluciones. Algunos trabajos recientes describen dificultades en cuanto a la especificación del punto de referencia en MOEA/D [4], [8], [9],[10]. Trabajos con MOEAs que incluyan un sub-división del espacio de los objetivos como la propuesta en este trabajo son muy escasos, sólo hemos encontrado [11], [12].

El problema de la mochila multiobjetivo en variables binarias (0-1 MOKP) es un problema combinatorio bien conocido y ampliamente manejado en la comunidad multi-objetivo. Un considerable número de métodos exactos y metaheurísticos, ver por ejemplo [3], [13], [14], intentan resolver este problema. En [15], se señala el elevado número de soluciones superpuestas (overlapping solutions) cuando los MOEAs se aplican a problemas combinatorios con muchas variables de decisión y baja dimensionalidad. La aparición de soluciones superpuestas cuando el Problema de la Mochila 0-1 (2-3 objetivos) se resuelve con un MOEA, tiene un significativo impacto negativo sobre la diversidad del frente aproximado final de soluciones no-dominadas alcanzado [15].

Se propone en este trabajo un híbrido de NSGA-II, el cual divide el espacio de los objetivos (OSD) en varias regiones utilizando la solución Nadir la cual es calculada en cada generación del algoritmo. Las distintas subdivisiones utilizan diferentes estrategias de optimización de las funciones objetivo. La idea que subyace es intensificar la diversidad de soluciones del frente óptimo aproximado de Pareto (POF) alcanzado, permitiendo que en cada generación del algoritmo, soluciones dominadas por los extremos del POF alcanzado puedan entrar en la población N no-dominada.

El resto del trabajo se organiza de la siguiente manera. En la sección 2 se presentan algunos conceptos básicos para entender mejor este trabajo. En la sección 3 se describe el método propuesto. Los resultados experimentales se detallan en la sección 4. Por último, en la sección 5 se presentan las conclusiones.

2 Conceptos básicos

En términos de minimización, un POM puede ser definido de la siguiente forma:

$$\begin{array}{ll} Min. & F(x) = f_1(x), f_2(x), ..., f_n(x) \\ s.a. & \\ & g_k(x) \leq 0 \qquad k \in (1, 2, ..., p) \\ & h_l(x) = 0 \qquad l \in (1, 2, ..., q) \end{array} \tag{1}$$

donde $F(x)$ es el vector de objetivos a minimizar y $n \geq 2$ el número de objetivos. Las ecuaciones $g_k(x) \leq 0$ y $h_l(x) = 0$ representan respectivamente p restricciones de desigualdad y q restricciones de igualdad. Los valores de x que satisfacen el conjunto de las $(p + q)$ restricciones, definen el espacio realizable S. El vector $x = (x_1, x_2, ..., x_m) \in S$ es un vector solución de m variables de decisión.

El conjunto de las imágenes de cada solución realizable en el espacio de la decisión, conforma el conjunto de soluciones realizables en el espacio de los objetivos $Z = f(S)$ definido como $Z = \{z_1 = f_1(x), ..., z_n = f_n(x), \ \forall x \in S\}$ y donde $z = (z_1, ..., z_n) \in R^n$ representa una solución realizable en el espacio de los objetivos.

Una solución $z^t = (z_1^t, z_2^t, ..., z_n^t) \in Z$ domina una solución $z^u = (z_1^u, z_2^u, ..., z_n^u) \in Z$ y se le conoce como Pareto-óptima si se verifican las siguientes condiciones:

1. $z_j^t \leq z_j^u \qquad \forall j \in (1, 2, ..., n)$
2. $\exists j \in (1, 2, ..., n) \ \ tal \ \ que \ \ z_j^t < z_j^u$

Al conjunto de soluciones Pareto-óptimas en el espacio de soluciones se le llama conjunto óptimo de Pareto y a su imagen en el espacio de objetivos frente óptimo de Pareto.

La solución Ideal z^I de un POM es un vector solución $z^I = (z_1^I, z_2^I, ..., z_k^I)$, construido con los mejores valores función objetivo de todas las soluciones del espacio de los objetivos (Fig. 1). Esta solución es en general inalcanzable.

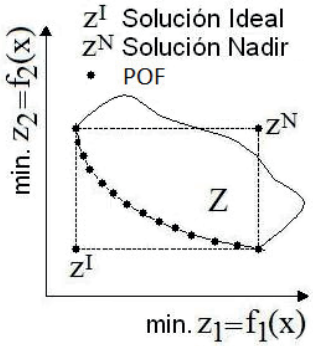

Fig. 1. Soluciones Ideal, Nadir y frente óptimo aproximado de Pareto (POF).

La solución Nadir z^N de un POM es un vector solución $z^N = (z_1^N, z_2^N, ..., z_k^N)$, construido con los peores valores función objetivo de todas las soluciones del frente de Pareto (Fig. 1). Esta solución puede ser alcanzable o inalcanzable.

2.1 MOEA/D con especificación de Zhang del punto de referencia

Básicamente, MOEA/D trabaja descomponiendo un POM en un número finito de sub-problemas escalares y resolviéndolos simultáneamente mediante la evolución de una población de soluciones. Algunos enfoques para convertir un POM en un sub-problema escalar se pueden consultar en [3]. El enfoque de Tchebycheff se expresa como sigue:

$$\begin{aligned} Min.\ \ & g^{te}(x|\lambda, z^*) = \max_{1\leq i\leq n} \{\lambda_i f_i(x) - z_i^*\} \\ s.a.\ \ & x \in X \end{aligned} \tag{2}$$

donde $z^* = (z_1^*, ..., z_n^*)$ es el punto de referencia (PR) especificado en este trabajo de la siguiente forma:

$$z_i^* = \alpha * max\{f_i(x)|x \in X\}\ para\ cada\ i = 1, ..., n \tag{3}$$

y donde $\alpha \geq 1$.

2.2 MOEA/D con especificación de Ishibuchi del punto de referencia

Ishibuchi et al. proponen en [8] usar en (2) la siguiente especificación para el PR:

$$z^R = z_i^* - \alpha_t(z_i^{max} - z_i^*) \tag{4}$$

donde $z_i^* = (z_1^*, ..., z_n^*)$ corresponde al mínimo valor en la función objetivo i, $z_i^{max} = (z_1^{max}, ..., z_n^{max})$ corresponde al máximo valor de la función objetivo i en la generación en curso y α_t es un parámetro que decrece en cada generación del algoritmo. De (4) es obvio que cuando $\alpha_t = 0$ los valores z^R y z^* tienen los mismos valores.

Para hacer que el valor z^R se aproxime gradualmente al valor del punto de referencia z^* durante la ejecución del algoritmo, el valor α_t es modificado en cada generación según:

$$\alpha_t = \alpha\ (t_{max} - t)/(t_{max} - 1) \tag{5}$$

donde α es un valor inicial de α_t, t_{max} es el número máximo de generaciones del algoritmo y t es la generación actual. Nótese que el valor final de α_t en la última generación es cero, i.e., z^R tiende a z^* durante la ejecución del algoritmo.

3 Método propuesto

El algoritmo propuesto en este trabajo consiste en una versión modificada de NSGA-II, en los siguientes términos:

1. En cada generación t del algoritmo: una población $R_t = P_t + Q_t$ es construida con P_t la población de padres de tamaño N y Q_t la población de hijos (tamaño N) generados de las operaciones de cruzamiento y mutación a partir de la población N construida en la generación $t-1$.
2. A partir de la población R_t la solución Nadir es identificada mediante algún método.
3. En base a la solución Nadir el espacio de los objetivos se divide en tres regiones independientes R_1, R_2 y R_3 tal como se indica en la Fig. 2.
4. Las soluciones de cada región R_1, R_2 y R_3 son clasificadas (complejidad computacional O(n2N)) en diferentes frentes no-dominados (F_1, F_2,...,F_n). Para la clasificación de las soluciones, se usan diferentes criterios de optimización de las funciones objetivo f_1 y f_2.
   (a) Región R_1: Las dos funciones objetivo f_1 y f_2 son siempre maximizadas.
   (b) Región R_2: La función f_1 es siempre maximizada. La función f_2 es maximizada si se cumple la condición $t \geq nt$, en caso contrario f_2 es minimizada. El valor t es la generación actual y nt un parámetro (número de generaciones que se maximiza o minimiza la función objetivo) que se define como:

$$nt = \alpha \; t_{max} \quad 0 \leq \alpha \leq 1 \tag{6}$$

   (c) Región R_3: La función f_2 es siempre maximizada. La función f_1 es maximizada si se cumple la condición $t \geq nt$, en caso contrario f_1 es minimizada.

   Finalizado el paso 4, toda la población R_t queda clasificada en frentes de no-dominación (F_1, F_2,...,F_n).
5. Para completar la población P_{t+1} hasta alcanzar un tamaño N, como en NSGA-II, las soluciones con menor rango primero, y mayor crowding-distance segundo, son escogidas.

4 Experimentos y comparaciones

4.1 Problema de la Mochila Multiobjetivo MOKP/0-1

El problema de la mochila multiobjetivo en variables binarias (MOKP/0-1) consiste en una serie de objetos o ítems con un peso, un beneficio asociado a cada uno de ellos y un límite de capacidad para cada mochila. Así, la tarea radica en encontrar el subconjunto de objetos que maximicen los beneficios totales de cada mochila y que puedan ser colocados en dichas mochilas sin exceder sus límites de capacidad. El problema es de complejidad NP-difícil y puede ser usado para modelar cualquier aplicación real que se ajuste al modelo descrito en (7).

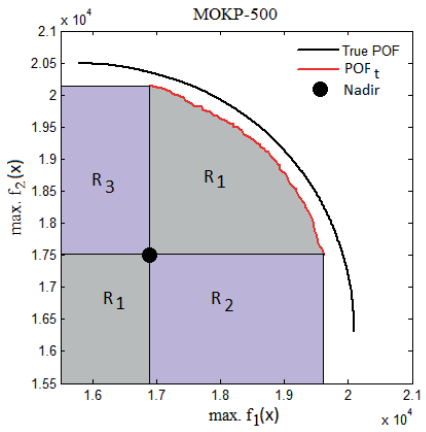

Fig. 2. División propuesta del espacio de los objetivos en base a la solución Nadir.

El MOKP/0-1 puede ser definido formalmente como sigue:

$$\begin{cases} max. \quad f_i(x) = \sum_{j=1}^{m} b_{ij} x_j \quad i = 1, ..., n \\ s.a. \qquad \sum_{j=1}^{m} w_{ij} x_j \leq c_i \qquad x_j \epsilon \{0, 1\} \end{cases} \tag{7}$$

donde: m=número de objetos, x_j=variable de decisión, n=número de sacos, b_{ij}=beneficio objeto j según saco i, w_{ij}=peso objeto j según saco i y c_i = capacidad saco i.

4.2 Configuración de parámetros y métricas

En este trabajo, las implementaciones de NSGA-II y MOEA/D se han realizado según [2] y [3]. Ambos algoritmos son aplicados sobre el 500-MOKP/0-1 con dos objetivos, los datos del problema y frente óptimo pueden descargarse de: https://sop.tik.ee.ethz.ch/download/supplementary/testProblemSuite/testProblemSuite/.

En todos los experimentos se utilizó codificación binaria, cruce uniforme de probabilidad 0.8 y probabilidad de mutación (bit a bit) de 1/500. Un número de 400000 evaluaciones de la función objetivo se usó como condición de parada. Tres tamaños de la población N=50, N=100 y N=200 soluciones fueron utilizadas en los tres algoritmos NSGA-II/OSD, NSGA-II y MOEA/D. Los valores examinados para el parámetro α definido en (6) de balance convergencia/diversidad de NSGA-II/OSD fueron α= 0.0, 0.1, 0.2, 0.3 0.4, 0.5, 0.6, 0.7, 0.8, 0.9 y 1.0. Con MOEA/D, los valores ensayados de α en el cálculo del punto de referencia z^* según la especificación de Zhang definida en (3) fueron α= 1.0, 1.05, 1.1, 1.15, 1.2, 1.25, 1.3; en la versión de Ishibuchi para el cálculo del punto de referencia

z^R definido en (4) y (5), los valores se fijaron en α= 0.0, 0.1, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0 y 10.0.

Para la comparación de los resultados obtenidos por los algoritmos, se emplearon la S-metric o hipervolumen H (punto de referencia usado el 0,0) sugerida en [16] y visualizaciones de los frentes de soluciones de Pareto alcanzados de valor H más próximo al valor medio final calculado en 30 ejecuciones independientes.

4.3 NSGA-II/OSD análisis previo: efectos de variar el parámetro α

En esta subsección se analizan las influencias en la convergencia y diversidad del frente de soluciones alcanzado, cuando se varía el parámetro α en la ecuación (6) en el algoritmo propuesto NSGA-II/OSD. En la Fig. 3 (izquierda), se muestran los valores del hipervolumen medio al modificar los valores del parámetro α. Se puede observar que los mejores valores de H se obtienen para valores intermedios del parámetro α así, el mejor valor del hipervolumen se alcanza cuando α=0.5. Para mejor interpretar estos resultados, la Fig. 3 (derecha) muestra los efectos sobre la distribución de soluciones del aproximado POF obtenido cuando N=200. Se observa que los frentes aproximados de Pareto de menor diversidad (mayor convergencia) y mayor diversidad (menor convergencia) se obtienen cuando α=0.0 y α=1.0 respectivamente; de otra parte, el mejor balance convergencia-diversidad se logra para un valor de α=0.5.

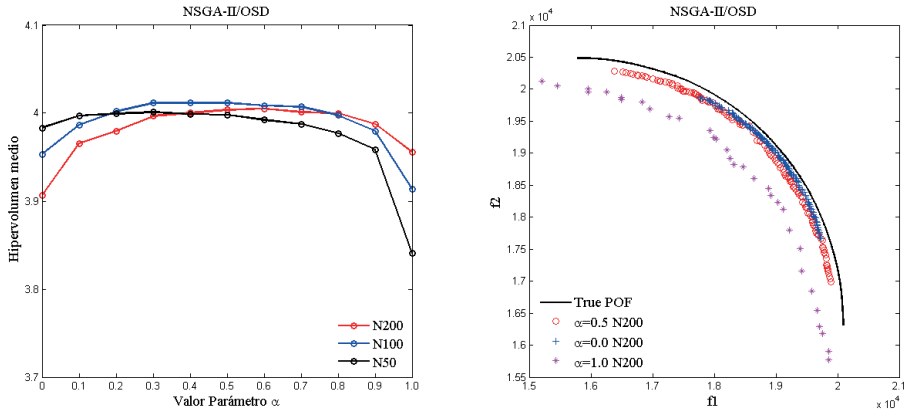

Fig. 3. Valores H al variar el parámetro α (izquierda) y gráficas de soluciones no-dominadas con el valor H más próximo al valor medio final en 30 ejecuciones (derecha).

Además, en la Fig. 4 se muestra la evolución del porcentaje de soluciones diferentes en la población N de soluciones para N=200 y valores α=0.0, α=0.5 y α=1.0. Se observa que el mejor valor porcentaje de soluciones diferentes logrado durante la evolución del algoritmo, se obtiene para α=1.0 lo cual explica la

mejor diversidad (aunque peor convergencia) del POF aproximado alcanzado y mostrado en la Fig. 3 (derecha). También, en la Fig. 4 se aprecia que durante la primera mitad de la evolución del algoritmo, el valor porcentaje de soluciones diferentes en N es mejor cuando se usa el valor α=0.5 en comparación con el valor logrado cuando se utiliza el valor α=0.0, más tarde, hacia el final de la evolución del algoritmo ambos valores se igualan. Esto explica el porqué de la mejor diversidad del POF aproximado alcanzado al final de la evolución y mostrado en la Fig. 3 (derecha), cuando se usa el valor α= 0.5 frente al valor α=0.0.

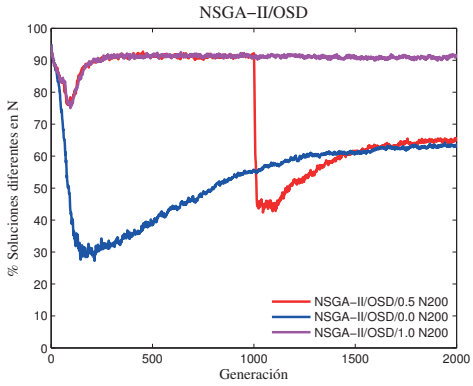

Fig. 4. Evolución de los porcentajes medios de soluciones diferentes en las poblaciones N en el algoritmo propuesto NSGA-II/OSD.

4.4 MOEA/D análisis previo: importancia de la especificación del punto de referencia PR

Dos especificaciones del punto de referencia, la de Zhang y la de Ishibuchi, descritas ambas en los apartados 2.1 y 2.2 se comparan en esta subsección. La Fig. 5 (izquierda) muestra los valores del hipervolumen medio H al variar el valor α en la especificación de Zhang del punto de referencia en MOEA/D según la ecuación (3). El valor H crece hasta un valor máximo (cuando α =1.2) para luego volver a decrecer. También, se puede observar en la Fig. 6 (izquierda) los efectos sobre la diversidad de los frentes de soluciones alcanzados cuando se utilizan los valores α=1.0 (mínima diversidad) y α=1.2 (máxima diversidad y máximo valor de H). Por ello, es altamente recomendable utilizar el valor α=1.2 en MOEA/D cuando se utiliza la versión de Tchebycheff y especificación de Zhang del PR.

Utilizando ahora en MOEA/D la especificación de Ishibuchi del punto de referencia según las ecuaciones (4) y (5) también, al variar el valor α se obtienen diferentes valores del hipervolumen H. La Fig. 5 (derecha) señala que el valor

H crece hasta un valor máximo (cuando $\alpha \geq 3$) a partir del cual permanece estable. Así mismo, se pueden observar, en la Fig. 6 (derecha), los efectos sobre la diversidad y convergencia de los frentes de soluciones alcanzados cuando se usan los valores α=0.0 (mínima diversidad y máxima diversidad), α=10 (máxima diversidad y mínima convergencia) y α=3 (valores de la diversidad y convergencia intermedios). También, en la Fig. 7 se puede ver que al incrementarse el valor α, el porcentaje medio de soluciones diferentes en la población N alcanzado por el algoritmo disminuye. Por lo cual, se recomienda usar el valor α=3.0 en MOEA/D cuando se utiliza la versión de Tchebycheff y especificación de Ishibuchi del PR.

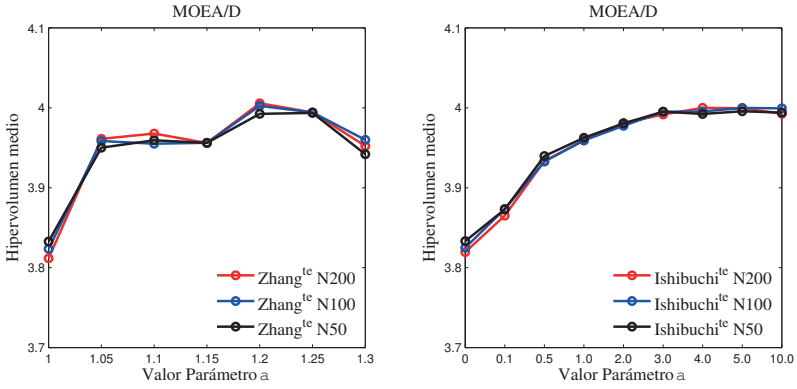

Fig. 5. Valores H al variar el parámetro α en la especificación de Zhang del PR en MOEA/D (izquierda). Valores H al variar el parámetro α en la especificación de Ishibuchi del PR en MOEA/D (derecha).

Por último, en la Fig. 5 (izquierda y derecha) se observa que utilizando las especificaciones de Zhang con el valor α=1.2 e Ishibuchi con valor $\alpha \geq 3$ en MOEA/D (versión Tchebycheff), se obtienen los mejores valores y ambos parecidos según el valor de la métrica H. También, la Fig. 8 muestra similares frentes de soluciones no-dominadas alcanzados por ambos algortimos; no obstante, durante toda la evolución del algoritmo siempre el número de soluciones diferentes en la población N, logrado usando en MOEA/D la especificación de Ishibuchi del PR es inferior al alcanzado utilizando la especificación de Zhang del PR, véase la Fig. 7.

4.5 Resultados comparativos: NSGA-II/OSD vs MOEA/D vs NSGA-II

En esta subsección comparamos el algoritmo NSGA-II/OSD propuesto en este trabajo, con los algoritmos MOEA/D con especificación de Zhang del PR y NSGA-II. Tanto en NSGA-II/OSD como en MOEA/D se utilizó aquel valor α que proporcionó el mejor valor del hipervolumen medio H tras 30 ejecuciones

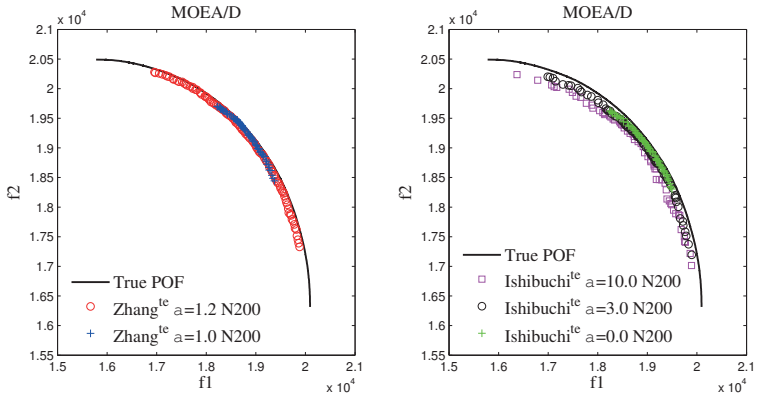

Fig. 6. Gráficas de soluciones no-dominadas con el valor H más próximo al valor medio final en 30 ejecuciones: especificación de Zhang del PR (izquierda), especificación de Ishibuchi del PR (derecha).

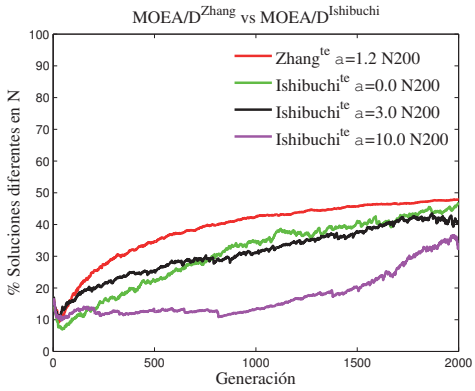

Fig. 7. Evolución de los porcentajes medios de soluciones diferentes en las poblaciones N en el algoritmo MOEA/D utilizando las especificaciones de Zhang e Ishibuchi del PR .

independientes y que según los experimentos descritos en anteriores apartados fueron α=0.5 para NASGA-II/OSD y α=1.2 para MOEA/D.

En la Fig. 9 (izquierda) se muestran los valores del hypervolumen alcanzado por los algoritmos durante su evolución. Se observa en dicha figura, que NSGA-II obtiene siempre el peor valor. Por otro lado, durante la primera mitad de la evolución, MOEA/D consigue un mejor valor de H con respecto al logrado por NSGA-II/OSD; luego, los valores H obtenidos por ambos algoritmos se igualan justo cuando, en las estrategias usadas con NSGA-II/OSD en las regiones R2 y R3 (Fig. 2) se maximizan los dos objetivos del problema. Idéntica conclusión se obtiene con las desviaciones del hipervolumen en la Fig. 9 (derecha).

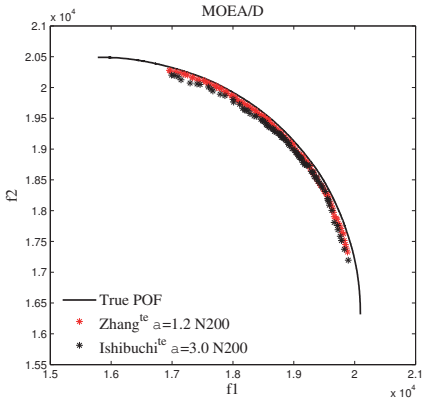

Fig. 8. Gráficas de soluciones no-dominadas con el valor H más próximo al valor medio final en 30 ejecuciones: especificación de Zhang del PR (α=1.2) y especificación de Ishibuchi del PR (α=3.0) .

Por último, en la Fig. 10 se muestran los frentes de soluciones no-dominadas alcanzados por los algoritmos. Se advierte en la figura, que NSGA-II logra una buena convergencia pero muy pobre diversidad de soluciones. Se observa también, que el frente de soluciones alcanzado con el método propuesto obtiene mayor diversidad que la alcanzada por MOEA/D con especificación de Zhang del PR, aunque en términos de convergencia es MOEA/D quien parece tener mejor valor. Estas diferencias, podrían explicarse por la diferencia del valor porcentaje de soluciones diferentes en la poblacion N logrado por los algoritmos durante sus evoluciones, véase la Fig. 11.

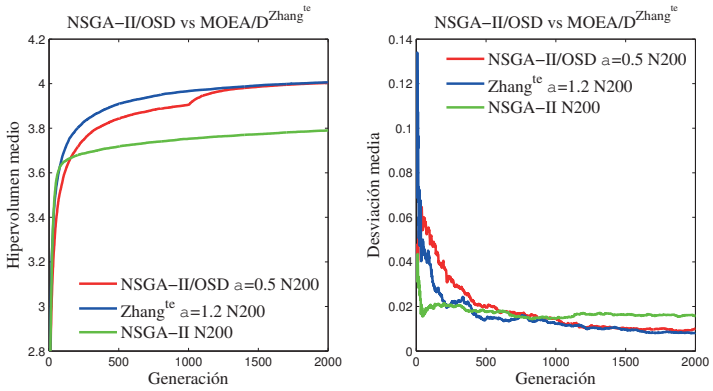

Fig. 9. NSGA-II/OSD versus MOEA/D versus NSGA-II: Evolución de los valores de los hipervolumenes medio (iquierda) y desviaciones del hipervolumen (derecha).

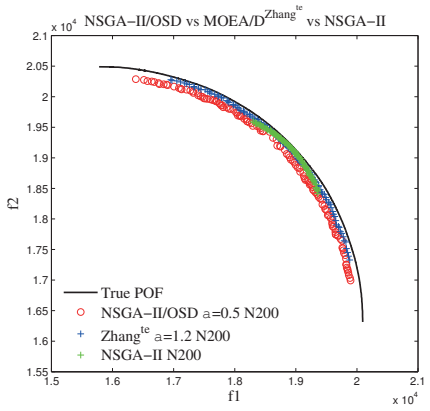

Fig. 10. NSGA-II/OSD versus MOEA/D versus NSGA-II: gráficas de soluciones no-dominadas con el valor H más próximo al valor medio final en 30 ejecuciones.

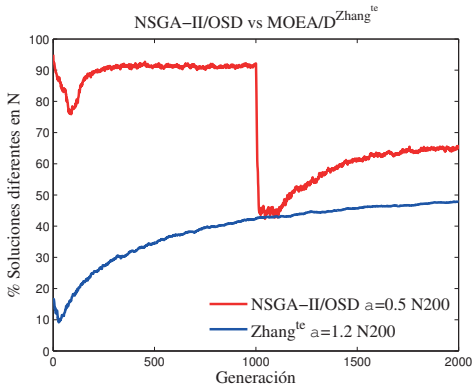

Fig. 11. NSGA-II/OSD versus MOEA/D: Evolución de los porcentajes medios de soluciones diferentes en las poblaciones N.

5 Conclusiones

En este trabajo se propone un algoritmo evolutivo multiobjetivo (NSGA-II/OSD) que hibridiza NSGA-II. El algoritmo subdivide el espacio de los objetivos en varias regiones utilizando la solución Nadir calculada en cada generación del algoritmo. Las distintas subdivisiones utilizan diferentes estrategias de optimización de las funciones objetivo. El algoritmo NSGA-II/OSD propuesto permite definir

un parámetro $\alpha \in [0, 1]$ muy fácil de usar, que permite balancear la diversidad/convergencia del frente de soluciones no-dominadas alcanzado por el algoritmo; para el valor α=0.5 el algoritmo logra su mejor valor de hipervolumen medio.

El algoritmo propuesto obtiene muy buen desempeño y mejores resultados cuando es comparado con NSGA-II. Cuando NSGA-II/OSD es comparado con MOEA/D con la especificación de Zhang del punto de referencia, en términos de la métrica del hipervolumen medio, ambos algoritmos obtienen valores similares. No obstante, NSGA-II/OSD logra una mayor diversificación de soluciones en el frente no-dominado final alcanzado, mientras MOEA/D parece alcanzar mejor convergencia.

Resumen En las Islas Canarias (España), región ultraperiférica de la Comunidad Europea, la explotación de las energías renovables, como viento, oleaje y sol, proporciona una mayor independencia energética. Para ello es necesario desarrollar modelos de predicción que optimicen el aprovechamiento de dichos recursos. Específicamente, con sistemas de energía undimotriz, la eficiencia de los mismos requiere del conocimiento futuro de las olas incidentes. Con este propósito, se propone en este trabajo la utilización de herramientas basadas en Deep Learning. Además, para la validación de la propuesta, se realiza una comparación de rendimientos entre modelos predictivos basados en redes neuronales recurrentes, concretamente una extensión de estas denominadas LSTM (Long Short Term Memory), y un modelo de predicción autorregresivo cuyos parámetros se calculan utilizando las ecuaciones de Yule-Walker. Se han utilizado dos series temporales de datos de oleaje con distintas características. Para evaluar la eficiencia de los modelos propuestos se ha utilizado el error cuadrático medio, obteniendo los mejores resultados con la red Vanilla LSTM.

Palabras clave: Deep Learning, Red Neuronal Recurrente (RNN), LSTM, Modelos Autorregresivos, Yule-Walker, Predicción de Oleaje

1 Introducción

En regiones insulares como las Islas Canarias (España), con sistemas eléctricos aislados, el aprovechamiento de recursos renovables como viento, oleaje y sol, disponibles en cantidades suficientes [1], contribuye a una mayor independencia energética. Esto se traduce en un menor consumo de combustibles fósiles, menor coste de la energía y menor huella de carbono.

En el año 2018, las Islas Canarias tenían una potencia total instalada de 3.308,6 MW dependiente de hidrocarburos y sus derivados, mientras que sólo

el 13,6% del total, unos 612,3 MW, se correspondían con fuentes de generación renovables [2]. Con esta situación de dependencia, el coste medio de la energía se situó en los 151,71 €/MWh [2]. Por otro lado, el coste de la energía eólica offshore aún no explotada lo suficiente y que requiere de estructuras flotantes para superar las difíciles batimetrías insulares, estaba entre los 82 y los 236 €/MWh [3], dependiendo de parámetros relevantes como la profundidad y la distancia a costa. De igual forma, el coste de la energía undimotriz aún en una fase muy prematura de desarrollo, se calculaba entre los 330-630 €/MWh [4] lo que la hacen económicamente inviable por ahora.

Un presumible descenso futuro de los costes de la energía eólica offshore y su instalación conjunta en plataformas híbridas eólica-undimotriz, con un menor coste medio conjunto al disponer éstas de una única infraestructura flotante así como compartir una única línea de evacuación de energía y mejorar la gestión de los recursos y sus variaciones [5], podrían situar el coste de la energía undimotriz entre los 113 y los 226 €/MWh para el año 2030 [4]. Ello originaría que la energía undimotriz fuese competitiva y pudiese formar parte de los sistemas de generación de energía en las Islas Canarias.

La energía undimotriz, de interés en este trabajo, es un recurso renovable y sostenible que aprovecha a través de sistemas convertidores de energía de las olas (WEC siglas en inglés), la energía contenida en el movimiento de las olas para la generación de energía eléctrica. Debido a las restricciones de diseño que imponen estos tipos de sistemas, el conocimiento y predicción del oleaje son de gran importancia [5], [6], [7]; además, su rendimiento energético puede incrementarse significativamente por ejemplo, mediante sistemas de control que permitan la entrada en resonancia de los dispositivos con el oleaje [8], [9]. No obstante, la predicción de oleaje no es trivial debido a la naturaleza del propio recurso y su comportamiento estocástico.

La predicción de oleaje se ha abordado con diferentes metodologías, entre ellas por ejemplo las que tratan de predecir la altura de ola significativa [9], [10]. En este trabajo se presenta un sistema de predicción de la altura de las olas en tiempo real y se comparan un modelo basado en redes neuronales con otro autorregresivo. El propósito es optimizar la generación de energía de las olas. Para ello, por un lado se entrenará una red neuronal recurrente (RNN siglas en inglés), las cuales han demostrado un rendimiento más general, flexible y adaptable que otros estimadores deterministas [11]. En particular se usarán redes Long Short Term Memory (LSTM siglas en inglés) muy atractivas, pues han evidenciado gran efectividad en aplicaciones con datos secuenciales. Esta metodología por otro lado, se compara con un modelo autorregresivo que utiliza las ecuaciones de Yule-Walker en el ajuste de parámetros.

El resto del trabajo se organiza de la siguiente manera. En la sección 2 se describen los datos y filtrado usados en este trabajo. La sección 3 presenta algunos conceptos básicos de redes neuronales LSTM y modelos de predicción autorregresivos. Los resultados experimentales se detallan en la sección 4. Por último, en la sección 5 se presentan las conclusiones.

2 Datos disponibles

El estudio de la predicción de oleaje se localiza en la isla de Gran Canaria (Islas Canarias), cuya situación geográfica es adecuada desde el punto de vista del aprovechamiento energético undimotriz [12].

La Isla de Gran Canaria ofrece un recurso undimotriz que se sitúa entre los 25 y 30 kW/m [13], inferior a emplazamientos de la costa Europea Atlántica pero igualmente significativo para su explotación. La mayor concentración de energía de las olas se sitúa en alturas entre los 1.5 m y los 3.5 m y períodos de entre 7 s y 13 s [14].

Los datos empleados provienen de observaciones reales provistas por la boya de medición Triaxys Las Palmas Este, operada por el organismo estatal Puertos del Estado cuyo identificativo es 1414, y está situada aproximadamente a 28.05° N y 15.39° W, sobre una profundidad de 30 metros, en la vertiente oriental de la isla.

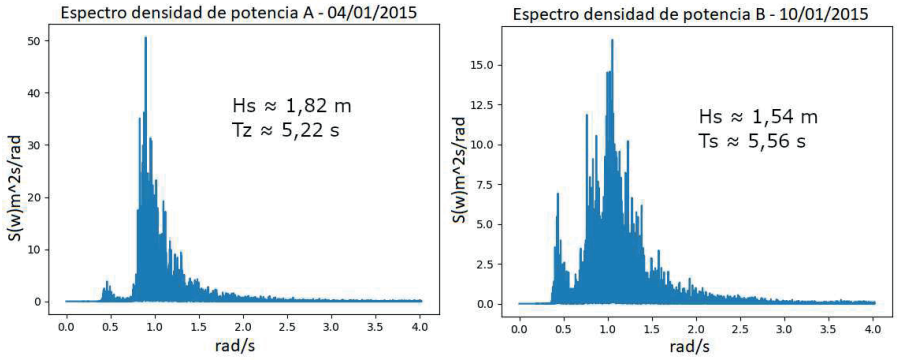

Fig. 1. Espectro del oleaje del conjunto de datos de la muestra: A) 4 de enero de 2015; B) 10 de enero de 2015.

La boya cuenta con una frecuencia de muestreo de 8.04 rad/s (1.28 Hz) Toma datos cada 0.78 segundos, en intervalos de 20 minutos cada hora de medición. Los dos sets de muestras con los que se cuentan pertenecen a los datos recogidos por la boya de medición los días 4 de enero, entre las 11:00 h y las 23:00 h (A), y 10 de enero del año 2015, entre las 00:00 h y las 11:00 h (B), para contar con muestras disímiles, en días y horarios alternos, con la intención de disponer de distintos espectros de oleaje. En total contamos con 36.267 mediciones en el conjunto de datos A, y 41.448 para el conjunto de datos B. Estos espectros de oleaje se representan en la Fig. 1, mostrando diferencias notables. No obstante, aunque ambos espectros están caracterizados por olas de baja frecuencia, en el conjunto de datos B se observa como existe una mayor componente de oleaje de alta frecuencia, lo que nos permitirá validar los modelos de predicción en dos situaciones dispares.

La principal característica que se obtiene del análisis de los datos (Fig. 1), es que gran parte de la energía contenida en las olas se concentra a bajas frecuencias, las cuales son más regulares y están menos afectadas por la no-linealidad [9]. De esta manera, se puede asumir una linealidad entre los valores pasados y futuros de oleaje, pues estos están estrechamente correlados con los posteriores y contienen una menor cantidad de ruido blanco en ellos.

2.1 Filtrado de datos

Estudios previos han demostrado la eficacia de realizar un filtrado a los datos de oleaje [9]. El filtro permite la eliminación de olas de alta frecuencia debidas a la acción localizada del viento y con muy baja energía, por lo que no interesa su predicción desde el punto de vista de un WEC. Por esta razón, a los datos disponibles, conjunto de datos A y B, se les aplicará un filtro de paso bajo de 0.4 Hz, frecuencia estimada como la más idónea para el estudio. La frecuencia de corte y sus implicaciones en el estudio del filtrado de los datos, están fuera del alcance de este trabajo.

3 Modelos de predicción

El objetivo del presente estudio es comparar los resultados obtenidos de una predicción de oleaje cuando se calculan con herramientas basadas en Deep Learning o de manera determinista. Para ello se compararon los resultados obtenidos del modelo mediante el uso de redes neuronales recurrentes (RNN), con los obtenidos utilizando un modelo autorregresivo aplicando el estimador Yule-Walker (YW).

3.1 RNN (LSTM)

Las redes LSTM constituyen un grupo dentro de las redes neuronales recurrentes (RNN), cuya aplicación principal es el procesamiento y predicción de datos dispuestos en secuencias y resultan adecuadas para aprender dependencias a largo plazo [15]. Por tanto, secuencias y dependencias como las que se disponen en una serie temporal de oleaje se prestan a ser modeladas con esta herramienta.

Una característica interesante que presenta una ventaja significativa sobre las redes neuronales tradicionales, es que la arquitectura de la red LSTM (Fig. 2) contiene una puerta de olvido (forget gate) e interconexión entre celdas, que les permite guardar información para procesarla posteriormente (para otras capas, otros inputs, con los que colaboran en la predicción de valores futuros), evitando así que las señales más antiguas se desvanezcan gradualmente durante el procesamiento (vanishing gradient). Esto les confiere un buen rendimiento en la predicción de series temporales, incluyendo el caso particular de las series de oleaje, como así se demuestra en los trabajos de Fan [10] y Hua [16].

En la Fig. 2 se muestra una red LSTM con los diferentes bloques dispuestos a modo de red conectada de forma recurrente. Los bloques contienen módulos

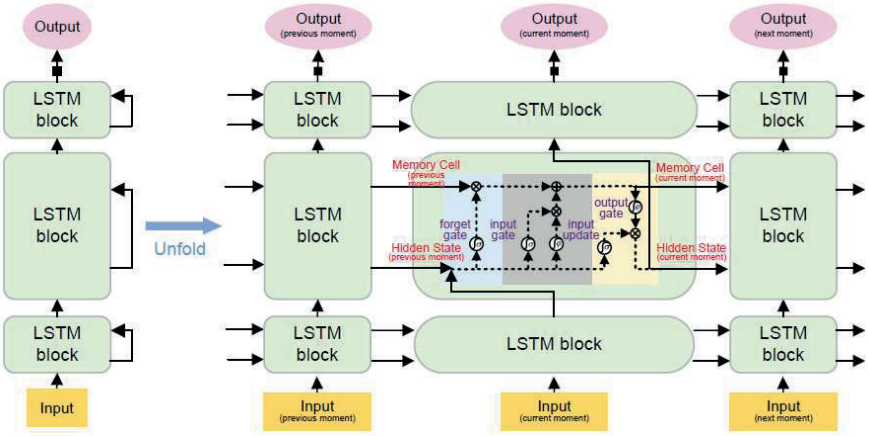

Fig. 2. Red LSTM de tres capas, que muestran las diferentes entradas y el flujo recurrente del que adquieren el nombre estas estructuras [16].

funcionales conformados por las celdas de memoria y sus respectivas puertas. Cada celda de memoria se encarga de recordar el estado temporal de la red neuronal y las puertas formadas por unidades multiplicativas son responsables de controlar el patrón del flujo de información [15].

Según las funcionalidades prácticas correspondientes, estas puertas se clasifican como la puerta de entrada, la puerta de salida y la puerta de olvido. Las puertas de entrada controlan la cantidad de novedad, información nueva que se transmite, es la información que fluye hacia la celda de memoria, mientras que la puerta de olvido gobierna la cantidad de información de la celda de memoria que aún permanece en la celda de memoria actual a través de la conexión recurrente. Por último, la puerta de salida determina cuánta información se usa para calcular la activación de salida del bloque de memoria [15].

Además de la configuración que se muestra en la Fig. 2, correspondiente a la configuración apilada o Stacked LSTM, se pueden disponer de arquitecturas de redes LSTM de manera diferente, con lo que se tendrían tres tipos que son Vanilla LSTM (V-LSTM), Stacked LSTM (S-LSTM), arriba citada, y Bidirectional LSTM (B-LSTM).

Una V-LSTM es un modelo LSTM que tiene una sola capa de unidades LSTM y una capa de salida utilizada para hacer las predicciones. En cambio, una LSTM apilada o S-LSTM se puede definir como un modelo LSTM compuesto por múltiples capas LSTM interconectadas (Fig. 2). Por último, las B-LSTM son aquellas que aprenden la secuencia de entrada hacia adelante y hacia atrás y concatena ambas interpretaciones. De esta forma, la capa de salida puede obtener información de estados pasados (hacia atrás) y futuros (hacia adelante) simultáneamente.

Las diferentes configuraciones no son más que diferentes interconexiones entre los bloques de celdas. Las conexiones entre bloques permiten que una deter-

Tabla 1. Resumen de las especificaciones adoptadas para cada una de los diferentes modelos V-LSTM, S-LSTM, B-LSTM y YW

Modelo	Características
V-LSTM	input layer = 32, lstm_1 layer = 32, output layer = 1 learning rate = 0.001, loss = error cuadrático medio optimizador = adam, epochs = 20, batch size = 70
S-LSTM	input layer = 32, lstm_1 layer = 32, lstm_2 layer = 32 output layer = 1, learning rate = 0.001, loss = error cuadrático medio optimizador = adam, epochs = 20, batch size = 70
B-LSTM	input layer = 32, lstm_bidirectional layer = 64, output layer = 1 learning rate = 0.001, loss = error cuadrático medio optimizador = adam, epochs = 20, batch size = 70
YW	input = 32, coeficientes = 33, output = 1

minada salida conforme inmediatamente el resultado, o sirva de entrada para el siguiente bloque. En nuestro estudio se analizarán las tres configuraciones, para obtener cuál de ellas puede ser más competitiva a la hora de realizar las predicciones con precisión.

En cualquiera de los casos, cualquiera de las configuraciones LSTM (ver Tabla 1) será de 32, es decir, el número de celdas será de 32, con sus respectivos módulos funcionales (input gate, forget gate, ouput gate), para estimar a partir de los 32 estados de oleaje de mar anteriores el estado siguiente (32 inputs), y con una función de activación del tipo tangencial hiperbólica (tanh) para la celda de salida. Esta configuración nos permitirá realizar una comparación con el modelo autorregresivo de orden 32 con ecuaciones de YW, que igualmente emplea los 32 estados anteriores para predecir el siguiente estado de oleaje (ver Tabla 1). Los parámetros de entrenamiento elegidos para cada una de las configuraciones son:

- Número de iteraciones (denominado epochs o épocas) igual a 20
- Tasa de aprendizaje (learning rate en inglés) de 0.001
- Función de pérdida: se considera el error cuadrático medio (RMSE)
- Algoritmo de optimización: se usa el descenso de gradiente eficiente denominado “adam” [17]
- Tamaño de lote (batch size en ingés) de 70

Con estos parámetros se asegura un buen número de muestras de entrenamiento antes de que se actualicen los parámetros internos del modelo.

3.2 Modelo Autorregresivo

El modelo de predicción determinista elegido es un AR autorregresivo (1), que impone una dependencia lineal entre los valores pasados y futuros. Por lo tanto,

el aumento de la onda de oleaje $\eta(k)$ dependerá de sus n valores pasados, siendo n el orden de modelo,

$$\eta(k) = \sum_{i=1}^{n} a_i \eta(k-i) + \xi(k) \tag{1}$$

donde se ha incluido el término de innovación $\xi(k)$. Con las ecuaciones YW [18] se estiman los parámetros a_i, siendo el término de innovación un ruido blanco con varianza σ^2.

Estacionariedad de la serie de tiempo. En primer lugar, se verificará que se cumplen las hipótesis de que las series de tiempo consideradas son estacionarias. Para ello se aplicarán los test estadísticos ADF (Augmented Dickey–Fuller) [19], [20] y KPSS (Kwiatkowski-Phillips-Schmidt-Shin) [21]. Hay que tener en cuenta que, en el test ADF la hipótesis nula es H0: "la serie temporal es no estacionaria", y en el test KPSS la hipótesis nula es H0: "la serie temporal es estacionaria". Por lo tanto, en el primer caso interesa obtener un p-valor pequeño (menor que 0,05) y en el segundo caso interesa obtener un p-valor no tan pequeño (mayor que 0,05). Realizados los test con los datos considerados en este trabajo (Sección 2), se obtuvo un p-valor inferior a 0,01 con el test ADF y superior a 1,0 con el test KPSS, lo que nos permite suponer que las series temporales son estacionarias.

Yule-Walker. Las ecuaciones YW [18] se usan para estimar los parámetros a_i (inferiores a la unidad y condición de proceso estacionario) que gobiernan el modelo autorregresivo (1), de modo que la mejor predicción con l pasos avanzados desde el instante k, se estima como se muestra en (2).

$$\widehat{\eta}(k+l|k) = \sum_{i=1}^{n} \widehat{a}_i \widehat{\eta}(k+l-i|k) \tag{2}$$

Los parámetros de las ecuaciones de YW se pueden obtener a través de la función de covarianza o a través de la función de correlación (y autocorrelación), que se muestra en (3).

$$Corr[y_t, y_{t-k}] = \frac{E[y_t - \mu][y_{t-k} - \mu]}{E[y_t - \mu]^2} = \frac{y_k}{y_0} = \rho_k \tag{3}$$

Por último, a partir de la función de autocorrelación se pueden estimar los parámetros que definen el modelo. Concretamente, resolviendo el sistema de ecuaciones (4) se calculan los valores de los parámetros a_i que gobiernan el fenómeno, los datos de oleaje, de manera que podamos estimar los valores futuros de la ola incidente con (2). En este caso n = 32, es decir, emplearemos un modelo de orden 32, que ya ha demostrado ser apto para este tipo de aplicaciones [22].

$$\begin{bmatrix} \rho_1 \\ \rho_2 \\ \vdots \\ \rho_{p-1} \\ \rho_p \end{bmatrix} = \begin{bmatrix} 1 & \rho_1 & \cdots & \rho_{p-2} & \rho_{p-1} \\ \rho_1 & 1 & \cdots & \rho_{p-3} & \rho_{p-2} \\ \vdots & & & & \\ \rho_{p-2} & \rho_{p-3} & \cdots & 1 & \rho_1 \\ \rho_{p-1} & \rho_{p-2} & \cdots & \rho_1 & 1 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_{p-1} \\ a_p \end{bmatrix} \quad (4)$$

4 Experimentos

En esta sección se exponen los resultados alcanzados con los dos modelos de predicción descritos, los basados en las redes LSTM con las diferentes configuraciones y el modelo autorregresivo con ecuaciones de YW. En ambos casos se emplean los 32 estados anteriores para conformar la siguiente predicción (orden del modelo de 32 en el caso del autorregresivo, 32 entradas en el caso de las LSTM) de manera que se equiparen los resultados.

Ambos modelos deben ser entrenados, a fin de obtener los parámetros óptimos que definen el fenómeno. En este punto, el entrenamiento de los modelos ya nos ofrece una primera conclusión, YW no requiere sino de los 32 estados anteriores para entrenarse y de 32 estados siguientes de test. En cambio, con este conjunto de entrenamiento tan limitado, 32 estados, la red LSTM sería incapaz de optimizar los parámetros necesarios. Por tanto, con LSTM, se opta por generar subconjuntos de datos, 5 en concreto, en los que 4 de estos subconjuntos conformarán el conjunto de entrenamiento y el restante será el conjunto de test. Para poder estimar el rendimiento se opta por un proceso de validación cruzada, en las que los subconjuntos se alternan de manera que se obtengan diferentes conjuntos de entrenamiento y test con los mismos subconjuntos. Para las muestras A y B (con filtro), el tamaño de los subconjuntos de entrenamiento es de 28.987 y 33.132 datos y de 8.283 y 7.247 datos, respectivamente, para los subconjuntos de test.

Los primeros resultados que se muestran son los de la red LSTM y las diferentes configuraciones descritas. Se evalúan a través de la raíz del error cuadrático medio (RMSE), la media de los diferentes subconjuntos de datos (folders) derivados de la validación cruzada y su desviación. Los resultados se muestran en la Tabla 2 para el conjunto de datos A, del 4 de enero de 2015, y la Tabla 3 para el conjunto de datos B, del 10 de enero del 2015.

Un análisis de los valores de las Tabla 2 y Tabla 3, indica que la configuración más simple, la V-LSTM, es la que mejores resultados ofrece con ambos conjuntos de datos. También, se observa que con cualquiera de las configuraciones existen diferencias entre los diferentes conjuntos de datos (A y B) en términos de rendimiento, asociado a los diferentes espectros del oleaje existente (ver Fig. 1), por lo que existe una relación entre el rendimiento (RMSE) y el estado del mar existente en cada momento durante las predicciones. Por otro lado, en las figuras (Fig. 3-5) se presentan las funciones de pérdida de las distintas redes LSTM, que muestran una buena optimización (loss bajo) y ausencia de sobreajuste (overfitting), es decir sin diferencia apreciable entre el coeficiente de

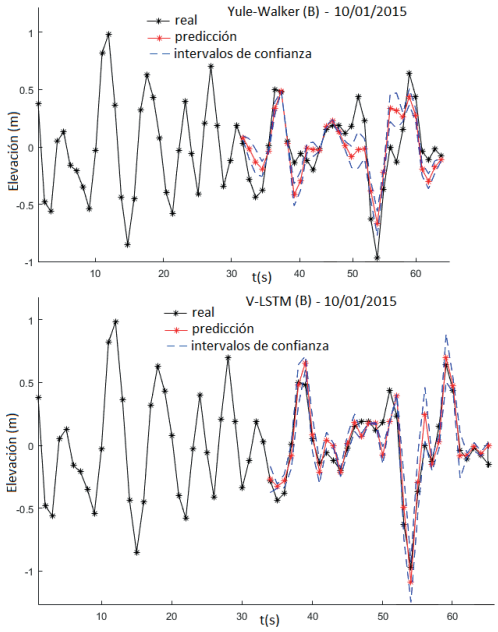

Fig. 7. Resultados gráficos temporales, arriba, Yuler-Walker, abajo, V-LSTM, para el conjunto de datos B.

perdidas (loss) de entrenamiento y el de test. La configuración V-LSTM, que es la más sencilla, requiere de un menor número de parámetros y ha demostrado, frente a las restantes configuraciones un mejor rendimiento y menor complejidad, aún así hablamos de optimizar 8.853 parámetros con la V-LSTM, por los 16.673 y los 16.705 parámetros de las configuraciones S-LSTM y B-LSTM respectivamente, un número elevado si comparamos con los 32 que se deben determinar en el proceso autorregresivo.

En el modelo autorregresivo estimado con las ecuaciones de YW, para igualar las condiciones de predicción del modelo neuronal, se seleccionaron al azar en las muestras de datos A y B, 32 estados de oleaje de mar a modo de entrenamiento, para realizar las siguientes 32 predicciones de manera continuada, con 5 selecciones aleatorias de las que se ha obtenido el error medio y la desviación. En ambos conjuntos de datos el error es superior en el modelo autorregresivo frente al modelo V-LSTM (ver Tablas 2-3-4), esta diferencia también se puede ver gráficamente realizando una predicción temporal (ver Fig. 6-7).

Finalmente, señalar que todas las mediciones de tiempos (entrenamiento y predicción) mostradas en las Tablas 2-3-4 han sido hechas en Intel Core i7-8550U, 1.8-4.0 GHz y 4 núcleos.

5 Conclusiones

En este estudio, se utilizan 3 configuraciones de redes LSTM y un método determinista AR-YW con dos conjuntos A y B de datos de oleaje, recogidos en las Islas Canarias en días dispares, para realizar un modelo predictivo del comportamiento del oleaje en condiciones ambientales oceánicas diferentes. Se utiliza el indicador error cuadrático medio (RMSE), para evaluar la precisión y la estabilidad de los resultados de la predicción alcanzados con los diferentes modelos, a partir de los dos conjuntos de datos.

Los experimentos mostraron que la red V-LSTM puede lograr resultados más precisos, con un menor error y más constantes que otras configuraciones LSTM y que el modelo AR-YW. Por ello la aplicación de redes LSTM es una metodología adecuada para la predicción de oleaje a corto plazo. No obstante, como sistema instalado en un generador undimotriz para predicción en tiempo real presenta algunas dificultades, como por ejemplo el coste computacional, Este se traduce en tiempos de entrenamiento mayores, dada la multitud de parámetros a estimar, 8.853, frente a los 32 utilizados por el modelo autorregresivo. Este mayor coste computacional, no debe ser un impedimento para desestimar las redes LSTM, pues los resultados están a su favor. No obstante, su utilización requiere de una buena estrategia de entrenamiento y predicción que desacople ambos procesos, de manera que el mayor coste no influya en el desarrollo de un sistema de predicción en tiempo real. Esto constituye una línea de trabajo futura.

Resumen
Se ha planteado e implementado un modelo no lineal para optimizar la cadena de valor apícola en el sudoeste bonaerense (Argentina) con el objeto de maximizar el Valor Actual Neto. La propuesta consiste en emplear un Algoritmo Genético anidado cuyo diseño contempla diferentes alternativas en la toma de decisiones. Con el fin de lograr una implementación eficiente, se han adoptado técnicas de programación paralela para explorar diferentes instancias simultáneamente. De esta manera, se logra identificar oportunidades para que la cadena de valor del productor apícola pueda obtener una ventaja competitiva.

Palabras clave: Cadena de Valor, Algoritmo Genético, Productor Apícola.

1 Introducción

El concepto de cadena de valor (CdV) fue desarrollado y popularizado en 1985 por Michael Porter [1], en su libro "Ventaja Competitiva: crear y sostener un desempeño superior". Dicho autor definió el valor como la cantidad que los compradores están dispuestos a pagar por un producto o un servicio que proporciona una empresa, y concibió la CdV como la combinación de nueve actividades estratégicas de valor agregado que operan dentro de una empresa y que trabajan en conjunto para proporcionar valor para los consumidores o usuarios.

A las primeras cinco actividades, Porter [1] las denomina primarias, las cuales se relacionan con la creación física del producto, y su venta y transferencia al comprador, así como la asistencia posterior a la venta (logística interna, operaciones, logística ex-

terna, mercadotecnia, y ventas y servicio). Las restantes cuatro actividades (de infraestructura de la empresa, administración de recursos humanos, desarrollo tecnológico y adquisiciones), Porter las denomina de apoyo, las cuales sustentan a las actividades primarias y se apoyan entre sí, proporcionando insumos comprados, tecnología, recursos humanos y varias funciones de toda la empresa.

Año tras año, el concepto de CdV ha sido objeto de abundante literatura. Siguiendo a Kippenberger [2], se denomina CdV al conjunto de actividades principales de una empresa, que se unen a través de eslabones, y a medida que el producto pasa por cada uno de ellos va añadiendo su valor. Por su parte, Kaplinksy [3], afirma que la CdV hace referencia a todas las actividades para que un producto o servicio, desde su concepción hasta sus distintas fases de producción - pudiendo involucrar distintas combinaciones de transformación física, de insumos y de diferentes servicios -, sea entregado a disposición del usuario o consumidor final y su posterior desecho. A medida que el producto se mueve de una actividad hacia la otra dentro de la CdV, añade valor al producto o servicio final [4].

Como tal, la CdV puede utilizarse como una herramienta para desglosar un negocio en actividades principales, permitiendo así la identificación de fuentes de ventaja competitiva [5]. El análisis de la CdV es un método utilizado para descomponer el conjunto en las actividades que lo conforman, con la finalidad de facilitar la toma de decisiones estratégicas, al ubicar a la empresa frente a sus clientes, proveedores y competidores. Dicho análisis proporciona recomendaciones útiles para ajustar las acciones y los procesos, con el objeto de dar el mayor valor posible al mercado destinatario y aumentar los márgenes de beneficio de la empresa.

La CdV elegida en el presente estudio es la apícola, específicamente la del SO bonaerense (Argentina). La Organización de las Naciones Unidas para la Alimentación y la Agricultura [6] (FAO, según sus siglas en inglés) define a la apicultura como la ciencia y el arte de la cría de abejas. Dicha actividad económica es valorada no sólo por los productos de alto valor biológico y los servicios a la polinización de cultivos, sino también por su contribución al desarrollo regional con generación de empleo rural y por las bajas barreras de entrada, particularmente en el eslabón primario.

Existen buenas razones para defender y preservar la actividad apícola. Por un lado, posee un alto impacto social dado que se trata de un medio de producción de subsistencia para muchas regiones de nuestro país, en las que los ingresos provienen de las exportaciones de miel que movilizan en parte la actividad comercial. Por otro lado, y no menos importante, la necesidad de contar con poblaciones importantes de insectos polinizadores, indispensables para la producción agrícola y la ecología local.

Adicionalmente, el sistema de valor apícola está conformado por diversas CdV, tales como la del productor apícola, las salas de extracción, los acopiadores, los fraccionadores, los exportadores, los productores de materiales e insumos y los oferentes de servicios técnicos especializados, y diversos subproductos de la colmena, como polen, jalea real, propóleos, apitoxina, cera, material vivo, entre otros. La apicultura, en su sentido amplio, aporta a la economía y a la sociedad mucho más que miel, y quizás en esas externalidades radiquen parte de los desafíos más relevantes del sector apícola argentino.

Si bien, de acuerdo al Ministerio de Agricultura, Ganadería y Pesca de la Nación [7], gran parte del territorio argentino es apto para el desarrollo de la actividad y presenta distintos potenciales productivos tanto para la miel como para los subproductos de la colmena, Buenos Aires es la provincia con mayor concentración de la producción. La misma cuenta con alrededor de 915 mil colmenas, según fuentes oficiales de la Secretaría de Agroindustria de la Nación, seguida por la provincia de Entre Ríos, con 572 mil colmenas, Santa Fe, con unas 295, Córdoba con números similares y La Pampa, con cerca de 208 mil colmenas.

A pesar de que Porter [8] conectó las CdV entre empresas para formar lo que llamó "sistema de valor", para el presente estudio se utiliza el concepto de CdV del eslabón primario del sistema mayor, es decir, de los productores apícolas, sin analizar el sistema de valor apícola en su conjunto. Esto abre una futura línea de investigación.

El objetivo de este estudio consiste en determinar las principales actividades que crean valor para los consumidores finales o clientes y las actividades de apoyo relacionadas de la CdV del productor apícola del sudoeste (SO) bonaerense. Para ello, se emplea un optimizador que permite contemplar las no linealidades subyacentes en los modelos económicos, de modo de servir como soporte de la toma de decisiones del productor con el fin de detectar oportunidades, que puedan crear una ventaja competitiva.

2 Modelo matemático de la cadena de valor apícola

2.1 Descripción de la cadena de valor apícola

Para realizar el presente estudio se utiliza como referencia la zona del sudoeste bonaerense (Argentina). Según los Fundamentos de la Ley del Sudoeste Bonaerense (LP 13.647), esta región representa aproximadamente el 25% del territorio de la provincia de Buenos Aires. No es pampa húmeda, sino que forma parte de las regiones semiárida, árida y subhúmeda-seca del país, con características climáticas y edáficas que la diferencian del resto de la provincia en cuanto a sus potencialidades y limitantes productivas primarias, y por lo tanto también, en cuanto a las ventajas comparativas, claramente inferiores al resto de la provincia. Esta cuenca melífera está integrada por los partidos de Guaminí, Adolfo Alsina, Coronel Suarez, Coronel Pringles, Coronel Dorrego, Saavedra, Tornquist, Puán, Coronel Rosales, Bahía Blanca, Villarino y Patagones.

La región nombrada en el párrafo precedente posee una característica diferencial: contiene a todos los actores del sistema de valor apícola, desde productores a comercializadores, desde servicios técnicos hasta provisión de insumos, desde operadores logísticos hasta entes de financiamiento, entre otros.

De acuerdo a Goslino (2017) [10], debido a que el sudoeste bonaerense continúa siendo una zona agrícolamente marginal, con orientación ganadera y por ende pastizales naturales y montes, el potencial apícola supera largamente a otras regiones del país (particularmente la zona núcleo, en la pampa húmeda) donde la intensa agriculturización y el uso de agroquímicos dificultan cada vez más la continuidad de la apicultura.

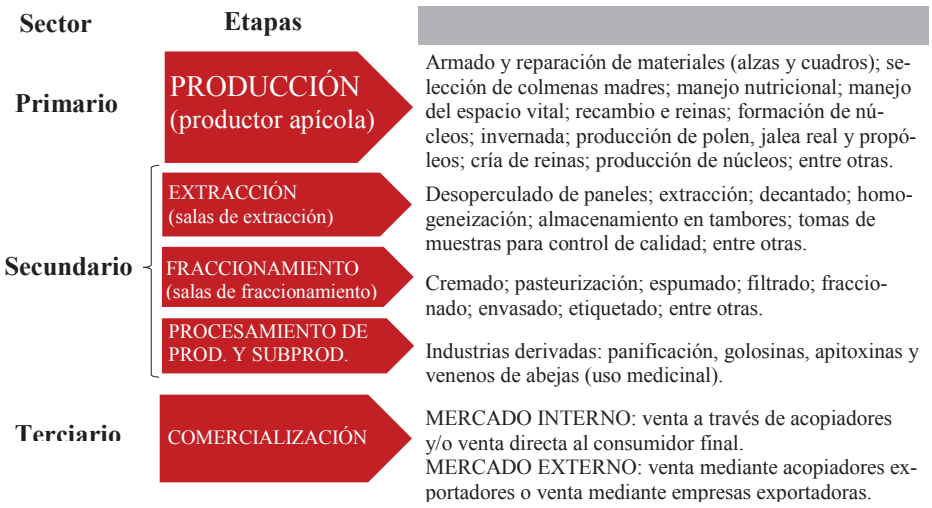

Fig. 1. Sistema de valor apícola.

Respecto al valor de los costos en los que incurre el apicultor, ya sean los directos de una actividad específica o los costos indirectos, son impuestos por los proveedores de insumos, las salas de extracción y las de fraccionamiento. En cuanto a los precios de venta, el productor apícola ofrece los productos y subproductos de su actividad a un precio fijado por el mercado, por ende, se lo considera tomador de precios. A efectos de este trabajo, se asume que el apicultor vende la miel a un precio único, ya sea al mercado destinatario interno o externo. En un entorno cambiante, la estructura de un proyecto apícola puede diseñarse teniendo en cuenta varias alternativas. En el modelo de CdV implementado en este trabajo, se han considerado únicamente las actividades estacionales resumidas en la Tabla 1.

Tabla 1. Actividades estacionales en la apicultura.

Actividad	Primavera (I)	Verano (II)	Otoño (III)	Invierno (IV)
Mantenimiento	☑	☑	☑	☑
Cosecha miel		☑		
Venta		Núcleos	Miel	
Producción de núcleos	☑			

En este trabajo únicamente se describe la primera etapa de desarrollo, que comprende la formulación e implementación del modelo matemático preliminar, la implementación del algoritmo genético anidado arriba descripto y los testeos necesarios. Por lo tanto, por razones de simplicidad, no se incluyen algunas actividades usuales ni ciertas variables pertinentes (p.ej. impuestos, regalías, entre otros) que complican el programa computacional. En la segunda etapa de desarrollo, se planifica incorporar términos que

contemplen otras actividades usuales, tales como los servicios de polinización y la redistribución de colmenas durante el invierno. Cabe destacar que en etapas posteriores deberán incluirse todas las variables relevantes y también las interrelaciones entre ellas expresadas en términos matemáticos. Así, esto permitirá que el modelo final sea realista, aunque dará lugar a un modelo matemáticamente más complicado.

3 Función objetivo

La función objetivo propuesta (Ec. 1) maximiza el valor actual neto (VAN) de las diversas actividades que componen la cadena de valor de la actividad apícola. El VAN se calcula como la suma de la inversión inicial I_0 y la sumatoria de la corriente de ingresos y gastos de las diversas actividades llevadas a cabo en las cuatro estaciones del año. A dicha sumatoria se la debe actualizar a la tasa anual de interés i_A, donde $y \in Y$ es uno de los años del horizonte temporal a evaluar.

$$VAN = -I_0 + \sum_{y=1}^{Y} (Invierno + Primavera + Verano + Otoño)(1 + i_A)^{1-y} \quad (1)$$

Las variables de decisión de este problema son el número y la disposición de las colmenas en cada campo $c \in C$ para cada año y $X_{y,c}$, y si produce material vivo para la venta $MV_{y,c}$. La inversión inicial I_0 consiste en el conjunto de bienes de capital necesarios para iniciar la actividad, tales como las herramientas de trabajo, el material vivo inicial, las colmenas y el vehículo para movilizarse entre los distintos campos. Eventualmente, algunos materiales deberán ser reemplazados, actualizándose en dicho momento a la tasa i_A.

Los flujos de ingresos y gastos de la actividad son eminentemente estacionales, y dichos montos se encuentran actualizados a la tasa cuatrimestral i_e. En el invierno, para la producción de miel, sólo se afrontan los costos indirectos asociados a la actividad de mantenimiento de las colmenas de dicha estación. En cambio, en dicha estación, para la producción de núcleos, comienza el período de una estimulación extra en la alimentación de las colmenas con el fin prepararlas para la reproducción, por lo que comienzan las erogaciones vinculadas a la producción de material vivo. En primavera, se originan las primeras erogaciones vinculadas a la producción miel y, sobre finales de dicha estación, las erogaciones de alimentación extra para producir material vivo finalizan. Luego, el valor actual de los ingresos y gastos en verano está conformado por la sumatoria actualizada de los ingresos por la venta de material vivo y de los costos de producción de miel. Las utilidades obtenidas en la estación otoño provienen de los ingresos por la venta de miel. En todas las estaciones el apicultor debe solventar gastos relacionados al mantenimiento de las colmenas $Mant_{y,c}^{e}$ (Ec. 2). Estos costos están mayormente relacionados a la mano de obra $ManoObra_{y,c}^{e}$, a la movilidad entre campos $Movilidad_{y,c}^{e}$ y a la alimentación de las abejas $CostoAzucar_{y}^{e}$, cuya cuantía varía según la época del año y la actividad llevada a cabo.

$$Mant_{y,c}^{e} = X_{y,c}\left(ManoObra_{y,c}^{e} + Movilidad_{y,c}^{e} + CostoAzucar_{y}^{e}\right) \quad \forall\, c = 1, C \quad (2)$$

Si el productor decide elaborar material vivo, esta actividad comienza al terminar el invierno y finaliza a fines de la primavera, aunque sus costos se erogan durante todo el año. La decisión de llevar a cabo esta actividad es registrada mediante la variable de decisión binaria $MV_{y,c}$, la cual toma valor unitario en el caso de que se decida llevar a cabo dicha actividad en el campo c durante el año y. El costo de producir el material vivo $CostoMV^e_{y,c}$ (Ec. 3) está vinculado a la mano de obra especializada ($ManoObraMV^e_{y,c}$) y a la alimentación adicional $CostoAzucarMV^e_y$ para las colmenas que se reserven para esta actividad N_y.

$$CostoMV^e_{y,c} = MV_{y,c}\ (N_y\ CostoAzucarMV^e_y + ManoObraMV^e_{y,c}) \qquad \forall\ y = 1, Y \text{ (3)}$$

El ingreso de esta actividad $InMV_{y,c}$ puede calcularse como la diferencia entre el precio de venta de cada núcleo $PrecioMV_y$ y los insumos necesarios para la venta $CostoMV_{y,c}$, multiplicado por la cantidad de núcleos producidos $ProdNucleos_{y,c}$ por las colmenas dedicadas a tal fin N_y.

$$InMV_{y,c} = MV_{y,c}\ N_y\ ProdNucleos_{y,c}\left(PrecioMV_y - CostoMV_{y,c}\right) \quad \forall\ y = 1, Y \text{ (4)}$$

La venta de miel en otoño está representada en la Ec. 5, calculada a través del producto entre la cantidad producida de miel $ProdMiel_{y,c}$ (en kg/colmena en función de cada campo); la cantidad de colmenas en cada campo $X_{y,c}$; y el margen bruto por kg. de miel. Este último viene dado por la diferencia entre el precio $PrecioM_y$ y los costos de venta por kg de miel $CostoM_{y,c}$.

$$VentaMiel = \sum_{c=1}^{C} X_{y,c}\ ProdMiel_{y,c}\ (PrecioM_y - CostoM_{y,c}) \quad \forall\ y = 1, Y \text{ (5)}$$

La variable de decisión asociada a la distribución de colmenas $X_{y,c}$ enfrenta restricciones referidas a la capacidad máxima de albergue de cada campo $XMax_{y,c}$ (Ec. 6) y al crecimiento del colmenar. El aumento del número de colmenas totales viene dado por una función f, eventualmente ni lineal ni derivable, que describe tanto el incremento natural como la incorporación y posible venta del stock productivo (Ec. 7).

$$X_{y,c} \leq XMax_{y,c} \qquad \forall\ c = 1, C; y = 1, Y \text{ (6)}$$

$$X_{y,c} = f(X_{y-1,c}) \quad \forall\ y = 1, Y \text{ (7)}$$

El apicultor comienza con un stock inicial X_0 (Ec. 8), cuya ubicación en las localizaciones alternativas se restringe por la cota máxima descripta anteriormente y una cota mínima $XMin$ (Ec. 9) que garantiza una escala de trabajo rentable por cada localización.

$$\sum_{c=1}^{C} X_{0,c} = X_0 \text{ (8)}$$

$$X_{y,c} \geq XMin \quad \forall\ y = 1, Y \text{ (9)}$$

Luego del primer año, el apicultor puede enfrentarse a la necesidad de mover colmenas entre campos. Debido a este esfuerzo, el costo de mudanza (Ec. 10) depende de la diferencia entre la cantidad real de unidades en un campo y la cantidad que debería haber según la función de crecimiento f aplicada sobre la cantidad del año anterior. Si esta magnitud supera las 25 colmenas, es valuada considerando el costo por colmena $CMud_y$.

$$CostoMud_{y,c} = \left[f\left(X_{y-1,c}\right)X_{y-1,c} - X_{y,c}\right] CMud_y \quad \forall\, y = 2, Y \tag{10}$$

4 Metodología

Hemos diseñado e implementado un modelo de cómputo paralelo en el cual varios hilos de procesamiento optimizan simultáneamente diversos escenarios que han sido definidos por un algoritmo Maestro (Master). Como los resultados provenientes de los Trabajadores (Workers) serán diferentes, el Maestro ordena las soluciones candidatas según su aptitud y sincroniza la operación de los procesadores, asignándole a cada uno desocupado otro escenario prometedor a resolver. Este método involucra la búsqueda de la solución de muchos subproblemas de optimización simples, de pequeña dimensión, en lugar del problema original. Cuando está disponible un sistema de cómputo paralelo, este método se vuelve mucho más atractivo porque los subproblemas simples pueden resolverse de manera simultánea.

Según el presente enfoque de búsqueda iterativa, la Fig. 2 muestra un diagrama de flujo de dicho optimizador con la estructura Master (1) -Workers (2). Para simplificar esta explicación, asumimos que hay K Trabajadores disponibles (k=1,2,…K). Cuando se introducen los datos para un problema de optimización, en la Estrategia de Búsqueda (1) el Maestro crea K individuos, los cuales tienen definidos diferentes parámetros en sus respectivos cromosomas. El Maestro reparte los individuos entre los trabajadores y cada uno se encarga de la Búsqueda de una Solución (2) de acuerdo a lo que el Maestro ha decidido en su Estrategia (1). Mediante la técnica de Algoritmos Genéticos (AG) [9], cada Trabajador (2) genera la población inicial correspondiente tomando como base el individuo patrón que le fue asignado y aplica los procesos de selección, cruzamiento y mutación, produciendo así nuevos individuos de la próxima generación. Así se producen un grupo de Soluciones Candidatas (4) independientemente, basadas en los diferentes tipos de individuos (3).

El Maestro (1) recibe información sobre las Soluciones Candidatas (4) y los valores correspondientes a su fitness, reordenándolas con un ranking de aptitud. Cuando es necesario buscar los candidatos de la próxima generación, la optimización de la Estrategia de Búsqueda (1) decide los individuos patrón (3) para la próxima Búsqueda (2). Si no hay necesidad de tomar más decisiones, el Maestro elige la Solución del candidato más apto como la Solución final del problema original de optimización. Aunque esta solución final, no es la solución óptima exacta en un sentido estricto en la mayoría de los casos, es simplemente una solución aceptable, que muestra un valor de idoneidad relativamente excelente dentro de un rango predeterminado.

En vez de aplicar representaciones tradicionales de los individuos del AG, todos los parámetros correspondientes a la toma de decisiones y todas las variables de optimización se representan juntos para conformar un único cromosoma. Por ende, nuestra propuesta emplea una estructura genética tal como se muestra en la Fig. 3. Para el k-ésimo individuo, la primera parte TD_k, referida a la toma de decisiones, tiene exclusivamente elementos binarios; mientras que el resto VO_k consta de genes que en este caso corresponden a números enteros. Esta estructura nos ha incentivado a definir estrategias especiales para los operadores genéticos.

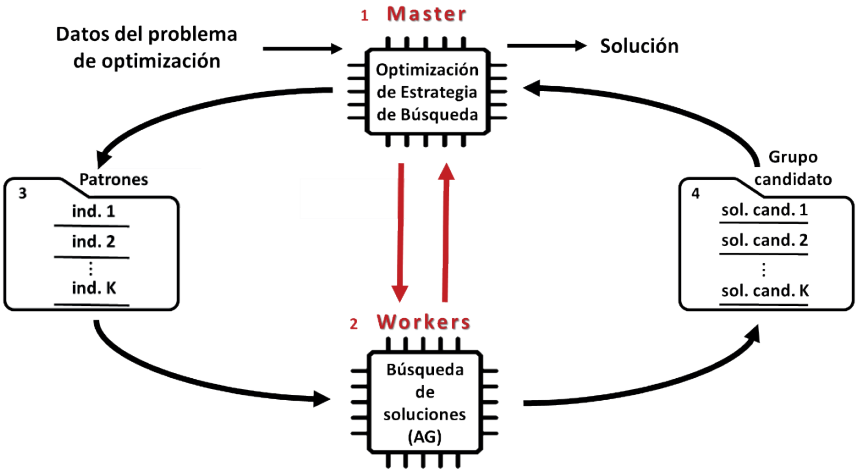

Fig. 2. Representación conceptual del optimizador.

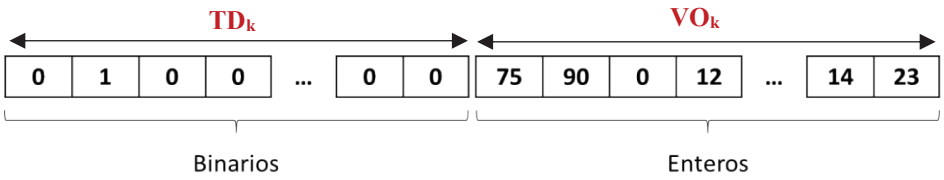

Fig. 3. Ejemplo de estructura genética del k-ésimo individuo.

El desafío que plantea un problema de optimización dinámico es la correlación temporal de las variables de decisión. En este sentido, los individuos generados por los operadores genéticos deben respetar la función que describe la trayectoria temporal. Sumado a esto, la existencia de restricciones vinculadas a la finitud de los recursos implica un reto para la creación de nuevas generaciones. Así, los operadores genéticos deben garantizar en todo momento la construcción de sujetos factibles para evitar ineficiencias en la búsqueda del óptimo.

La población inicial es construida a partir de la formación de individuos que satisfagan las restricciones impuestas al caso de estudio. La distribución de colmenas es determinada aleatoriamente para el primer año, y los años siguientes son proyectados

compatibilizando lo ya obtenido mediante las operaciones genéticas. Específicamente, la estrategia para la obtención de las generaciones posteriores se puede resumir en las siguientes etapas:

PASO 1) **Selección** aleatoria de los padres y del período temporal a modificar.

PASO 2) **Cruzamiento o Mutación.** Aplicación de alguno de los operadores genéticos elegido aleatoriamente en el período seleccionado.

PASO 3) **Compatibilización**. Modificación de los períodos posteriores al cambio introducido por los operadores genéticos, respetando el desarrollo de la variable de decisión dictada por la función o heurística.

PASO 4) **Cambio poblacional**. Nuevo ordenamiento en función del fitness y eliminación de los peores individuos hasta alcanzar la cantidad de la población al inicio del procedimiento.

Se itera sobre estos pasos hasta cumplir con alguno de los siguientes criterios:

- Número máximo de iteraciones donde el mejor individuo no se altera.
- Número máximo de iteraciones.

Para seleccionar los padres (PASO 1), la población es ordenada en función de su valor de fitness. Tomando en cuenta ese orden, una mayor chance de selección es otorgada a aquellos individuos con mayor fitness. Por ejemplo, en la Figura 3 se muestra el caso donde se seleccionan al azar dos individuos de un problema de localización de colmenas en 3 campos posibles a lo largo de 3 años. Cada gen representa un campo, agrupándose 3 genes por cada año. Luego, el segundo año resulta elegido aleatoriamente para aplicar la operación de cruzamiento. A modo ilustrativo, el total de colmenas iniciales (para t=1) de cada individuo es 82, asignadas a cada campo aleatoriamente. Si tomamos un ejemplo sencillo donde la tasa de crecimiento es del 10% lineal, cada individuo tendrá 90 colmenas en el segundo año y 99 en el tercero. La evolución del número de colmenas sigue la distribución determinada en el período inicial.

En cuanto al operador de cruzamiento (PASO 2), las parejas seleccionadas deben ser distintas en al menos 2 genes para el período elegido al azar. De esta forma se garantiza que la permutación de valores no altere la cantidad total de colmenas en los hijos resultantes. Una vez que dos individuos compatibles son seleccionados, se eligen aleatoriamente dos genes cuyas cantidades sean distintas entre los padres y cuya diferencia tenga signo opuesto. Luego, el cruzamiento se realiza tomando el valor mínimo de la diferencia entre los genes a intercambiar. Esta manipulación es necesaria para garantizar que los cromosomas tengan sentido físico. En el caso de estudio, este procedimiento asegura que el número de colmenas de los individuos resultantes respete la cantidad total que debería haber para ese período. Más aún, el cruce entre genes con una misma posición asegura que nunca se supere la cantidad máxima permitida de colmenas en cada campo.

En el caso ilustrado en la Figura 4, el i-ésimo gen del padre 1 difiere en la cantidad de colmenas asignadas al i-ésimo gen del padre 2 para i =1…3. Dado que ambos individuos tienen un total de 90 colmenas a redistribuir en el segundo año y difieren en al menos 2 genes entre sí, existe al menos un gen donde las cantidades de colmenas es superior al del otro individuo para el mismo campo (+30), y existe otro gen donde la cantidad es inferior (-10). Al permutar el mínimo de la diferencia entre el par de genes

(10) se asegura que la cantidad de colmenas en los hijos resultantes continúe siendo 90. El ejemplo planteado propone permutar los genes 2 y 3 en t=2.

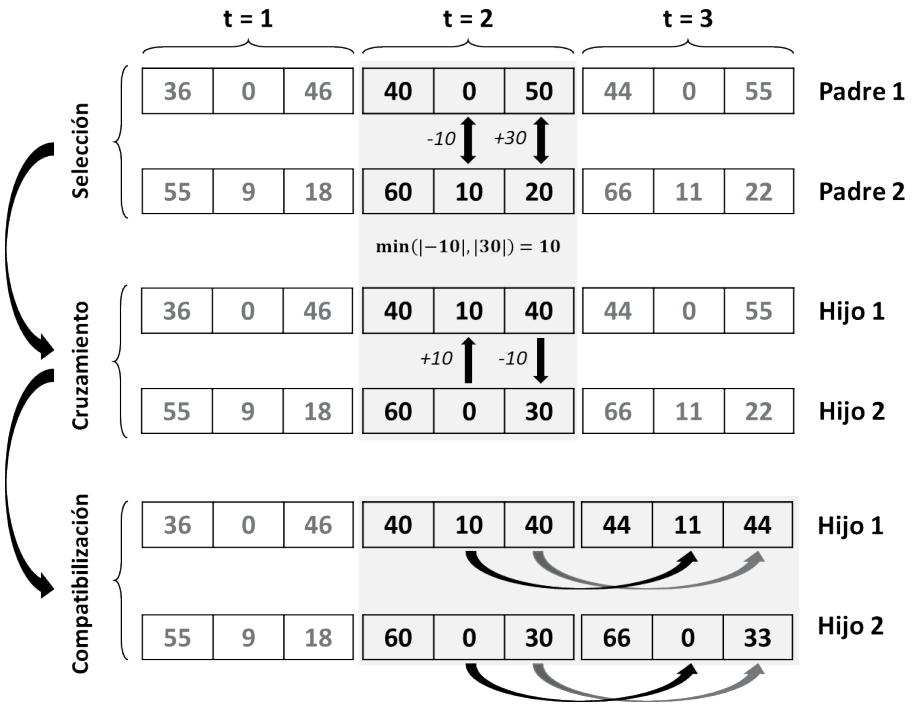

Fig. 4. Ejemplo de funcionamiento del operador de cruzamiento.

Con respecto al operador de mutación, la cantidad del gen elegido al azar de un individuo es asignada aleatoriamente a otro gen cuya cantidad es nula. Puede suceder que el gen de destino tenga una capacidad máxima inferior a la cantidad que recibirá. Si este fuese el caso, la cantidad excedente sobre el máximo se redistribuye sobre los restantes genes con valores positivos para obtener un individuo con una configuración más eficientes desde los puntos de vista económico y logístico. Cuando no existiesen genes con capacidad para recibir el remanente, este excedente se asigna al azar a otro gen con cantidad nula.

El ejemplo de la Figura 4 ilustra a ambos hijos luego de haber efectuado un cruzamiento. En particular, el segundo gen del Hijo 2 tiene valor positivo en el primer año (9), luego presenta un valor nulo en el segundo período, y finalmente vuelve a tener valor positivo en el tercero (11). Es decir, si únicamente se introdujese la modificación del operador cruzamiento, esto implicaría que las colmenas vuelven a su ubicación original en el tercer año. En términos de la representación del problema, esto podría reflejar un decisor que reversa sus decisiones constantemente. Esta aparente indecisión subyacente en la construcción de nuevos individuos es enmendada asumiendo que los cambios que introducen los operadores genéticos se mantienen hasta el final del período

bajo análisis. En el PASO 3, el tercer año se calcula nuevamente siguiendo la evolución del total de colmenas (99 unidades) en base al reordenamiento del segundo período.

5 Resultados

La complejidad del problema implementado es función del número de colmenas iniciales que el productor debe asignar a cada campo. Para la configuración de los hiperparámetros se consideró un proyecto de 500 colmenas iniciales, 30 campos potenciales en el sudoeste bonaerense (sujetos cada uno de ellos a restricciones de capacidad) y un horizonte temporal de 5 años. La selección de los hiperparámetros fue implementada utilizando un procesador Intel i7, simulando 200 casos por alternativa. La cantidad de hijos producto de la aplicación de los operadores genéticos equivale al 10% del tamaño de la población.

Se determinó que el algoritmo logra encontrar el óptimo asequible en un porcentaje superior al 68% de las veces cuando el tamaño de la población supera los 800 individuos (Figura 5). Cuando el tamaño de la población alcanza los 1200 individuos, el algoritmo encuentra dicho máximo con una probabilidad del 88%. No obstante, existe un compromiso entre precisión y velocidad de procesamiento. Mientras que una población con 800 individuos alcanzó el óptimo asequible demorando aproximadamente 86 segundos, la población con 1200 individuos encontró dicho óptimo siempre, pero duplicando el tiempo de cómputo.

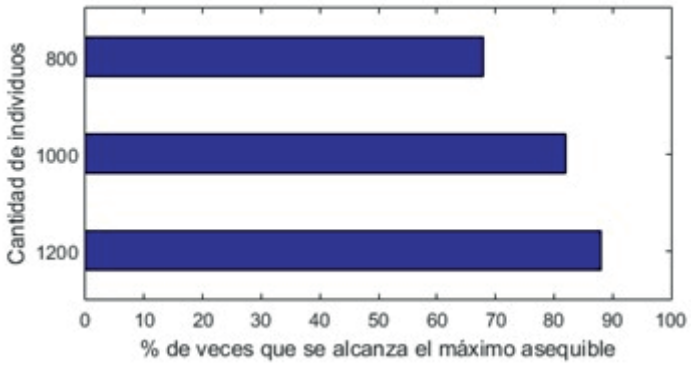

Fig. 5. Análisis del tamaño de la población.

La Figura 6 muestra que la mejor combinación se alcanza con una tasa de 10% de mutaciones para una población de 1000 individuos. Sin embargo, el máximo asequible tiene altas chances de ocurrencia a partir de una tasa del 40%.

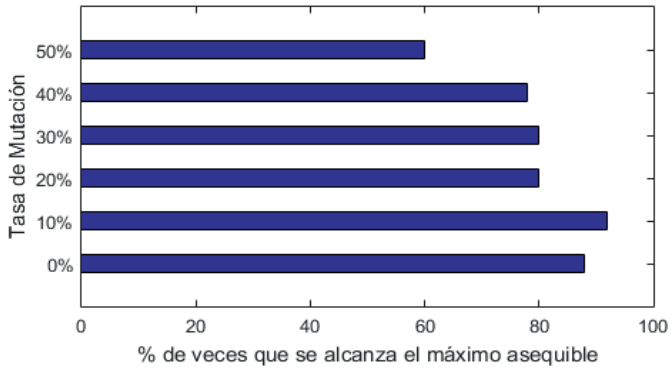

Fig. 6. Análisis del operador Mutación.

Con respecto a la velocidad del algoritmo, la implementación paralela logra reducir considerablemente los tiempos de procesamiento. Utilizando un procesador AMD FX(tm)-8120 con 8 núcleos reales, se ejecutaron 40 simulaciones por cada núcleo adicional utilizado. Tomando en cuenta la configuración óptima de los hiperparámetros, el cálculo del Speedup indica que el desempeño con 6 núcleos reduciría en hasta un 70% los tiempos de optimización en comparación con la ejecución secuencial. Más específicamente, la razón en cuestión alcanzó los 3.7 puntos.

La Figura 7 muestra la evolución del Speedup, denotándose un aumento decreciente de esta razón ante el uso de una mayor cantidad de núcleos. Cabe destacar que, si se considerase el problema base de 500 colmenas iniciales, un aumento del número de colmenas implicaría una disminución relativa de los valores de Speedup.

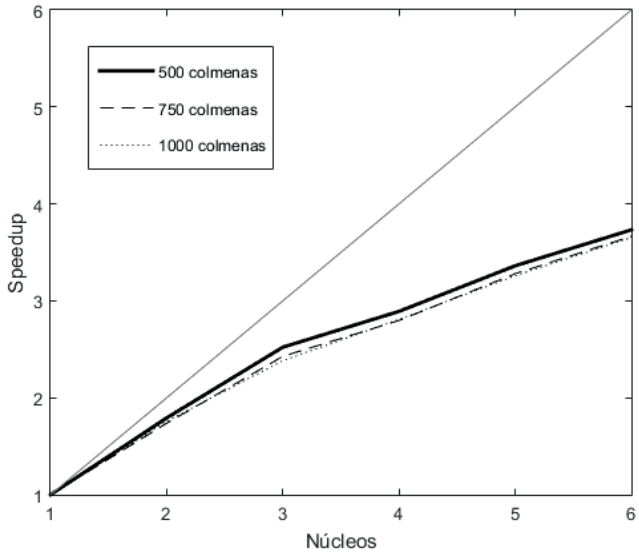

Fig. 7. Velocidad de procesamiento paralelo.

En la Figura 8 se representan los 30 campos alternativos en los cuales el productor apícola puede colocar sus colmenas. Cada uno de ellos posee una capacidad mínima de 30 colmenas y una máxima que depende del tamaño y la zona donde esté localizado el campo. Como lugar de residencia del productor se selecciona la ciudad de Bahía Blanca, representada a través del ícono violeta.

Una solución óptima factible dada por el AG consiste en colocar, en el primer año, una determinada cantidad de colmenas para la producción de miel en los campos 14, 15, 23, 28 y 30, representados a través de los íconos celestes. Es conveniente aclarar que una vez que se selecciona un campo, el mismo seguirá utilizándose hasta colmar su capacidad máxima. Conforme la aclaración anterior, para el segundo año se emplean los mismos campos que para el primer año. Luego, para el tercer, cuarto y quinto año, además de los campos del segundo año, se adicionan los campos 22 y 24, representados a través de los íconos amarillos. Los campos cuyo ícono son de color negro, corresponden a los que el AG en ninguna de sus soluciones eligió como candidatos posibles con el objeto de maximizar el VAN.

Fig. 8. Mapa con campos alternativos para el productor apícola.

Para el presente análisis, se supone que del total de colmenas que posee el productor, 150 de ellas podrán ser destinadas a dicha subactividad, en el caso que se decida llevarla a cabo. Cuando se utiliza esa cantidad de colmenas en la producción de núcleos para su posterior comercialización, la producción de miel por colmena se reduce. El AG confeccionado para este caso propone llevar a cabo esta subactividad en todos los años y considera los campos 14, 15, 23, 27, 28 ó 30 como posibles alternativas equiprobables para dicha producción. En cualquiera de ellos, el productor coloca un total de 150 colmenas que se utilizan tanto para la producción de núcleos y miel para la venta. El VAN máximo encontrado por el AG es de, aproximadamente, U$S 23.606.

6 Conclusiones

El objetivo de este estudio consiste en maximizar el valor actual neto (VAN) del eslabón primario de la cadena de valor apícola del sudoeste bonaerense, con el fin de determinar cuáles son las principales actividades que generan mayor valor a dicha producción, de modo de brindar un soporte a la toma de decisiones del productor.

Para ello, se ha diseñado e implementado un modelo de cómputo paralelo definido por un algoritmo Maestro (Master), el cual ordena las soluciones candidatas presentadas por Trabajadores (Workers) según su aptitud. Se determinó que el tamaño de la población requiere 1200 individuos para encontrar el óptimo asequible en el 88% de las simulaciones efectuadas. Respecto al operador mutación, la mejor combinación se alcanza con una tasa de 10% de mutaciones. Por último, en cuanto a la velocidad del algoritmo genético (AG), la implementación paralela logra reducir considerablemente los tiempos de procesamiento. Los resultados muestran que el VAN máximo encontrado por el AG es de, aproximadamente, U$S 23.606.

El AG aquí propuesto es una técnica de optimización para problemas dinámicos con restricciones, donde las decisiones de producción y localización pueden cambiar a lo largo del tiempo. Se busca que este modelo de cómputo pueda servir como soporte a la toma de decisiones del productor apícola con el fin de detectar oportunidades que puedan crear una ventaja competitiva. Este trabajo abre una futura línea de investigación que se centrará en estudiar, a partir de mejoras e introducción de nuevas variables y parámetros al AG propuesto en la presente investigación, el sistema de valor apícola, considerando todos sus eslabones.

Abstract. Additive manufacturing (AM), particular powder bed fusion (PBF), technologies have been utilized as an advanced direct digital manufacturing approach in the on-demand production of parts for end-users. It has been predicted that, by 2030, the industry-specific AM production resources will be shared by a significant number of small and medium enterprises across all industries to achieve higher machine utilization. By then, most of the orders from customers will be processed via online 3D printing service platforms while the parts will be manufactured with distributed AM resources near to the customers. The order acceptance and scheduling (OAS) problem in on-demand production with multiple AM machines has been discussed in our previous work and the mathematic model, as well as a heuristic dynamic OAS approach, was proposed to obtain promising average profit per unit time (APT) during the whole makespan by applying properly decision-making strategies. However, the proposed mathematic model only considered the operating costs. In this paper, the mathematic model and the heuristic approach are retrofitted by considering the idle costs of AM machines to investigate the relationships between the number of AM machines and total profit can be obtained under various market demand. The experimental results indicated that, for specific market demand, the total profit obtained is not always rising as the increasing of AM machines but dropping after a certain number of AM machines.

Keywords: Order Acceptance and Scheduling, On-demand Production, Heuristic, Decision-making, Powder-bed Fusion

1 Introduction

Additive manufacturing (AM), particular powder bed fusion (PBF), technologies have been utilized as an advanced direct digital manufacturing approach in the production of

parts for end-users where can be found nowadays in various industries like aerospace and defence, biomedical, and automotive industries [1-5]. Two of the most representative PBF processes for producing of industrial level metal parts are Selective Laser Melting (SLM) and Electron Beam Melting (EBM) where thermal energy source either a laser or electron beam is used to melt and fuse selectively regions of a powder bed (ASTM:F2790-12a). Both SLM and EBM have received significant attention in the research and have been widely used in various industries for advanced applications due to their advantages of fine resolution and high quality of printing near-full density parts [2,3]. Recently, more and more manufacturers provide online 3D printing services, such as 3D Hubs, PROTOLABS, i.materialise, etc, where the customers upload their designs and place orders if they satisfy with the quote and printability feedback from the service providers. This development will put the practical order acceptance and scheduling (OAS) problems on to the table in dealing with on-demand production orders from customers around the world. Although the topic of OAS has attracted considerable attention from those who study scheduling and those who practice it over the last decades [7,8], the OAS problems in production with PBF is barely discussed.

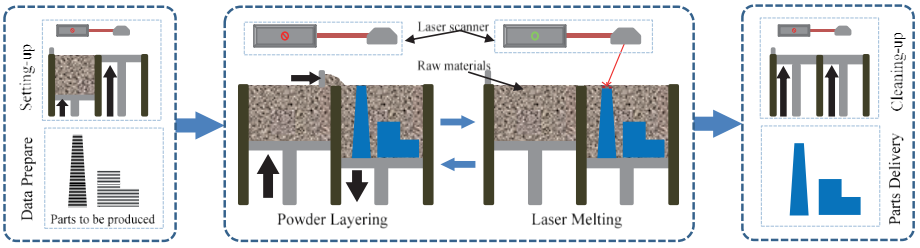

Fig. 1. Illustration of the general production process with PBF system.

The general process as shown in Fig. 1. Illustration of the general production process with PBF system. and characteristic of production with PBF systems have been introduced in our previous works [9-13], where a PBF system is treated as a kind of batch processing machine (BPM) in which a batch of identical or non-identical parts can be processed simultaneously according to the machine's capacity. Production with PBF systems is similar to a serial batch scheduling problem where the processing time of each batch is a function of jobs' attributes. The producing of a batch of parts with PBF system is usually called an AM job, and the processing time as well as the cost of the job not only depends on the total material volume of parts assigned to the job but also significantly affected by the maximum height of the parts. This makes the production planning and scheduling of AM jobs more difficult as the production time of an AM job is unascertainable before all the parts assigned to the job got confirmed. The unique characteristics of production with PBF systems have been analysed in our previous work [11], and the related works both in OAS and batch processing problems (BPP) have been reviewed as well. Although various approaches have been developed for various OAS problems and BPP problems, it is hard to adopt these approaches directly in on-demand production with PBF systems due to the unique nature of AM production [11].

Regarding the characteristics of production with PBF systems, the dynamic OAS problem in on-demand production with multiple PBF AM machines was defined and mathematically modelled with constraints of orders' arrival time and the due date for the first time in our previous work [11], and a strategy-based heuristic decision-making approach was proposed for the generation of feasible schedule solutions. The experimental results indicated that, with a given service price and due date, promising profitability can be obtained by applying properly decision-making strategies. However, the idle costs of AM machines were not considered thus the total profit obtained always increasing as the increasing of the number of AM machines. In reality, an idle cost, usually caused by site use fees and cost of capital, occurs no matter whether the machine is running. Therefore, more AM machines will defiantly obtain more revenue by processing more orders, but also cause more idle costs which might reduce the total profit.

In this paper, the mathematic model of dynamic OAS problem in on-demand production with multiple PBF AM machines is retrofitted based on our previous work by considering the idle costs of each AM machine. The rest of the paper is organized as follows. The problem addressed in this paper is defined and modelled mathematically in Section 2. In Section 3, the heuristic procedures for the generation of feasible schedule results, as well as the decision-making strategies to obtain better solutions, are proposed. An experimental study is designed and conducted with the proposed heuristic procedures and various decision-making strategies to demonstrate the relationships between obtained total profit and the number of AM machines under specific market demands in Section 4, followed by conclusions and future research direction in Section 5.

2 Problem statement

2.1 Problem definition and assumptions

This paper studies the dynamic OAS problem in an on-demand additive manufacturing environment where a set of part orders $\boldsymbol{N}$**={1,2,3,…,n}** are randomly placed by customers in chronological order, and the service provider with a set of AM machines $\boldsymbol{M}$**={1,2,3,…,m}** makes decisions on which part order should be accepted and how to schedule the accepted part orders simultaneously to maximize the average profit-per-unit-time (***APT***) obtained during the whole makespan. To further specify the problem addressed in this paper, the following assumptions are made:

- The machines considered in this paper are PBF systems with SLM/EBM processes used for metal parts production which can only handle one AM job at a time, and all the machines are available at the beginning;
- The part orders received by the service providers are from those customers satisfied with the service price and would like to place the orders if the parts can be delivered by the promised due date. Otherwise, the customers will either further negotiate with the service provider for a new offer or turn to another service provider;
- A part order is regarded as one digital model which has been properly oriented with necessary support structures according to the requirements of SLM/EBM

process, and the bottom side of the digital model needs to be put onto the building platform of the machine;

- A batch of parts assigned to a machine's job is feasible only when the parts can be placed in the machine without overlapping with each other which can be measured with the boundary box of a part order's digital model, and all the parts assigned to a machine's job will be processed simultaneously;
- A specific idle cost based on the site use fees and capital costs occurs along the time on each AM machine no matter whether it is running.

2.2 Mathematics model and constraints

The notations and decision variables used to formulate the mathematical model of the dynamic OAS problem in on-demand production with PBF AM machines are given in Table 1 and Table 2.

Table 1. Notations and decision variables.

Notations	Descriptions
i, j, k	The index used for part orders $i \in N$, AM jobs $j \in N$, and PBF machines $k \in M$
h_i, l_i, w_i, v_i, r_i	The boundary height, length, width, material volume, and the arrival time of part order i
W_k, L_k, H_k	The maximum width, length, and height of building space on machine k
ST_k, VT_k, HT_k	The time for setting up a new job, forming per unit volume of material, and coating per unit height of material respectively for machine k
HC_k	The cost of human work per unit time for machine k
TC_k	The operation cost per unit time for machine k
MC_k	The cost of per unit volume of material on machine k
IC_k	The idle cost per unit time for machine k
PV_k	The service price per unit volume of material for machine k.

Table 2. Decision variables used

Decision variables	Descriptions
$JST_{k,j}, JCT_{k,j}$	The start and completion time of the j^{th} job on machine k
$JPP_{k,j}$	The profit obtained from the j^{th} job on machine k
$JPC_{k,j}, JPT_{k,j}$	The production cost and time of the j^{th} job on machine k
MS	The makespan of the schedule
APT	The average profit per unit time of the schedule
$X_{k,j,i}$	Variable to determine if part order i is accepted and assigned to thej^{th} job on machine k
$Y_{k,j}$	Variable to determine if the j^{th} job on machine k is assigned with any parts
t	The system time $t \in [0, T]$

The objective of the dynamic OAS problem in on-demand production with multiple PBF AM machines is to maximize the total profit obtained within the makespan for the whole system which results in the maximize of the average-profit-per-unit-time (represented as ***APT***). The makespan of the whole system ***MS*** is defined as the time duration from the start of the first AM job to the completion of the last AM job. While the total net profit is calculated as total profit obtained through scheduled AM jobs minus the total idle costs of all the AM machines. Particularly, the idle cost of the AM machine k, represented as $\boldsymbol{IC_k}$, is the costs occurs no matter whether the machine is running such as the site use fees, cost of capital and management fees. While the production costs are caused due to the operation, materials and energy consumption, which occurs only when the machine in using The models of production cost, as well as the production time of an AM job are adopted from our previous work [11,13]. The objective function of the dynamic OAS problem by considering the idle costs of machines can be formulated as follows:

$$\boldsymbol{max\ APT} = \frac{\sum_{k\in M}\sum_{j\in N} \boldsymbol{JPP_{k,j}} - \sum_k (\boldsymbol{MS}\cdot \boldsymbol{IC_k})}{\boldsymbol{MS}} \tag{1}$$

Where

$$\boldsymbol{MS} = \max_{k\in M, j\in N}\{\boldsymbol{JCT_{k,j}}\} - \min_{k\in M, j\in N}\{\boldsymbol{JST_{k,j}}\} \tag{2}$$

$$\boldsymbol{JPP_{k,j}} = (\boldsymbol{PV_k} - \boldsymbol{TC_k}\cdot\boldsymbol{VT_k} - \boldsymbol{MC_k})\cdot\sum_{i\epsilon N}\boldsymbol{v_i}\cdot\boldsymbol{X_{i,k,j}} - \boldsymbol{TC_k}\cdot\boldsymbol{HT_k}\cdot\max_{i\epsilon N}\{\boldsymbol{h_i}\cdot \boldsymbol{X_{i,k,j}}\} - \boldsymbol{ST_k}\cdot\boldsymbol{HC_k}\cdot\boldsymbol{Y_{k,j}} \tag{3}$$

In the environment of on-demand production with PBF systems, several constraints are considered in scheduling part orders to PBF AM machines (detailed constraints please refer to our previous work [11]):

- Part orders can be assigned to an AM job on a PBF machine only when they can be placed on the machine's building platform without overlapping with each other, and any part order is not higher than the maximum height supported by the machine;
- A part order can only either be assigned to an exact AM job on a particular PBF machine or be rejected, and the machine can only handle one AM job at a time thus the AM jobs have to be scheduled to the machine in sequence;
- A part order is available for scheduling only after its arrival thus the start time of an AM job should be no earlier than any part order's arrival time assigned to the job, and the completion time of the job should be no later than the promised due date of any part order in the job.

3 Heuristic procedures and decision-making strategies

3.1 Heuristic procedures for dynamic OAS

The problem of dynamic OAS is a joint decision on order acceptance and BPM scheduling both of which have been proved as strong NP-hard problems. Additionally, the

generation of a feasible schedule solution, in particular batching part orders to form an AM job, is an extremely complicated procedure when considering the constraints of the machine's capacity as well as the arrival time and due date of each part order. Therefore, heuristic procedures are proposed in our previous work to generate feasible schedule solutions for solving the dynamic OAS problem efficiently. A feasible schedule solution is generated with two repetitive steps. Firstly, each AM machine will try to form a potential feasible AM job temporally through selecting available part orders from a waiting list where one part order can be selected by any AM machine simultaneously. Secondly, one of the potential feasible AM jobs will be selected and confirmed for production when either time limits or capacity limits were reached. Particularly, a Python function implemented by Jacobs [21] is used to measure whether a part could fit in a machine's building platform by considering the parts already included in the job. The Python function is capable to calculate whether a basket of rectangles (defined with the width w_i and length l_i of each part) could fit in a larger rectangle (defined with the width W_k and length L_k of the machine's building platform). Once an AM job was confirmed, all the part orders assigned to this job will be removed from the waiting list and any other potential feasible AM jobs will be reset by removing all the temporally assigned part orders. Also, a part order will be rejected if it has not been assigned to any machine until none of the machines can produce it by the promised due date. These two steps will keep repeating until no available part order waiting for scheduling. The heuristic procedures are illustrated in Fig. 2.

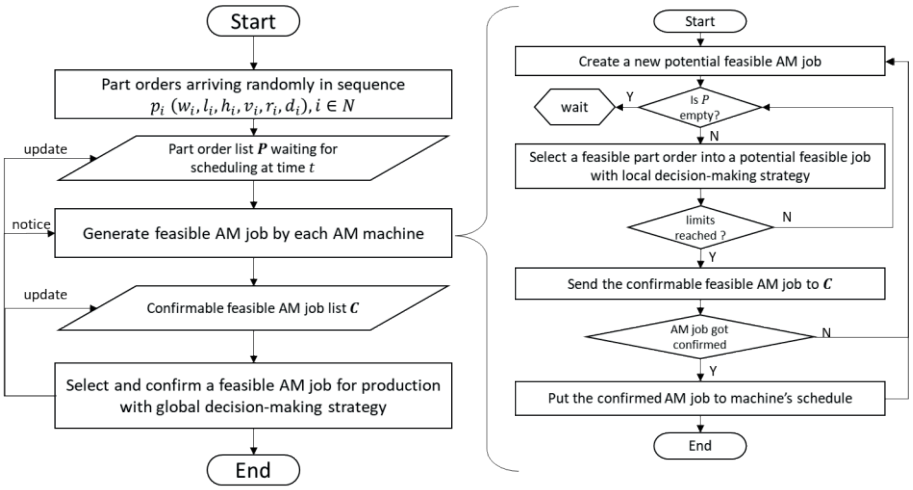

Fig. 2. Heuristic procedures for dynamic OAS in on-demand production with PBF systems.

One of the most important decisions need to be made is to confirm when is a potential feasible AM job ready for scheduling to a machine. An AM job can process a batch of non-identical parts simultaneously, and the production time of the job is a function of the properties of all parts assigned to this job as well as the specifications of the AM

machine to conduct this job. The available time slot for a feasible AM job, which is illustrated in Fig. 3, is constrained by the possible earliest start time of the job and the earliest promised due dates to the part orders assigned to the job.

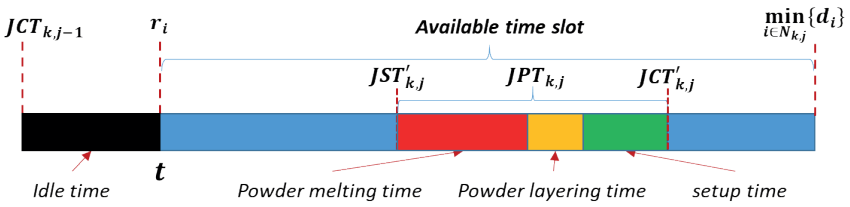

Fig. 3. An available time slot for an AM job in scheduling.

An AM job can be started when the previous job scheduled to this machine has been completed, and also the start time of the job could not be earlier than the current time t. We say an AM job is feasible so long as its start time and completion time are located within its available time slot. At the time moment t, the available time slot $TS_{k,j}$ for the j^{th} job on machine k can be formulated as follows:

$$TS_{k,j} = [max\{t, JCT_{k,j-1}\}, \min_{i \in N_{k,j}}\{d_i\}] \tag{4}$$

A feasible AM job should be considered to be confirmed for production when the time limits are reached no matter whether the machine still has available capacity to accommodate another part order. The time limits can be measured as follows:

$$\min_{i \in N_{k,j}}\{d_i\} - \max\{t, JCT_{k,j-1}\} \leq JPT_{k,j} \tag{5}$$

where $N_{k,j}$ is the set of parts assigned to the j^{th} job on machine k.
However, in the case of the time limits is not reached yet but no part orders can be fitted into the machine any more, which is called capacity limits, the feasible AM job also should be considered to be confirmed for production. Once an AM job has been confirmed, the start time of the job $JST_{k,j}$ should be adjusted to the earliest possible available start time that is $max\{t, JCT_{k,j-1}\}$, and accordingly the completion time of the job $JCT_{k,j}$ equals $JST_{k,j} + JPT_{k,j}$. The production time of an AM job can be calculated as follows:

$$\boldsymbol{JPT_{k,j} = VT_k \cdot \sum_{i \epsilon N} v_i \cdot X_{i,k,j} + HT_k \cdot \max_{i \epsilon N}\{h_i \cdot X_{i,k,j}\} + ST_k \cdot Y_{k,j}} \tag{6}$$

3.2 Decision-making strategies

Dynamic OAS in on-demand production with multiple PBF systems is a strong NP-hard problem where it is hard to generate all the possible schedule results within a reasonable duration particular for the problems with a big number of part orders and AM machines. Therefore, in our previous work [11], a set of decision-making strategies were proposed for the selection of available part orders to form a potential feasible AM

job as well as for the selection of potential feasible AM jobs to schedule. The performance of different decision-making strategy has been evaluated by compressing the schedule results with the best and worst results generated by randomly selection of part orders and AM jobs.

Three local decision-making strategies, named ***LPMS, LPPT, LFIFO***, and two global decision-making strategies, named ***GPMS*** and ***GPPT***, were proposed for the selection of part orders and selection of feasible AM jobs respectively. The combination of global and local decision-making strategies results in total six different strategy sets named ***GPMS-LPMS, GPMS-LPPT, GPMS-LFIFO, GPPT-LPMS, GPPT-LPPT***, and ***GPPT-LFIFO*** respectively which is described in **Table 3**. The experimental results indicated that it is practical to obtain promising APT as well as total profit for dynamic OAS in on-demand production with multiple PBF systems by applying properly decision-making strategies. The best schedule result for each test problem always can be obtained by applying one of the proposed decision-making strategy set, and particularly the APT obtained with GPMS-LPPT strategy set is 29.1% higher in average than the best results with random selection for all the 20 tested problems.

Table 3. Decision-making strategies for OAS in on-demand production with PBF systems.

Strategy set	Descriptions
GPMS-LPMS	Select part order with maximum $PMS_{k,j}^{i}$ and select feasible AM job with maximum $PMS_{k,j}$.
GPMS-LPPT	Select part order with maximum $PPT_{k,j}^{i}$ and select feasible AM job with maximum $PMS_{k,j}$.
GPMS-LFIFO	Select part order with minimum r_i and select feasible AM job with maximum $PMS_{k,j}$.
GPPT-LPMS	Select part order with maximum $PMS_{k,j}^{i}$ and select feasible AM job with maximum $PPT_{k,j}$.
GPPT-LPPT	Select part order with maximum $PPT_{k,j}^{i}$ and select feasible AM job with maximum $PPT_{k,j}$.
GPPT-LFIFO	Select part order with minimum r_i and select feasible AM job with maximum $PPT_{k,j}$.

To select a new part order i into a potential feasible AM job j on machine k, the average profit per unit time to be obtained by this job during the whole makespan represented as $PMS_{k,j}^{i}$ and the ratio of the production time of this job to the whole makespan represented as $PPT_{k,j}^{i}$ are considered as decision variables. Also, the arrival time of the part order r_i is considered as decision variable which may reduce the idle time of the machine. The $PMS_{k,j}^{i}$ and $PPT_{k,j}^{i}$ can be formulated as follows:

$$\boldsymbol{PMS_{k,j}^{i}} = \frac{\boldsymbol{JPP_{k,j}^{i}}}{\boldsymbol{JST_{k,j}^{i}+JPT_{k,j}^{i}}} \tag{7}$$

$$\boldsymbol{PPT_{k,j}^{i}} = \frac{\boldsymbol{JPT_{k,j}^{i}}}{\boldsymbol{JST_{k,j}^{i}+JPT_{k,j}^{i}}} \tag{8}$$

Where $\boldsymbol{JPT}_{\boldsymbol{k,j}}^{\boldsymbol{i}}$, $\boldsymbol{JPP}_{\boldsymbol{k,j}}^{\boldsymbol{i}}$, and $\boldsymbol{JST}_{\boldsymbol{k,j}}^{\boldsymbol{i}}$ represents the production time, profit and start time of the job j if part order i was assigned to this job. Accordingly, if the job j was scheduled to machine k, the profit per unit time to be obtained during the whole makespan represented as $PMS_{k,j}$ and the ratio of total production time to the whole makespan represented as $PPT_{k,j}$ are considered as decision variables to select a potential feasible AM job for scheduling. The $PMS_{k,j}$ and $PPT_{k,j}$ can be formulated as follows:

$$\boldsymbol{PMS}_{\boldsymbol{k,j}} = \frac{\sum_{\boldsymbol{k\in M, j\in N}} \boldsymbol{Y}_{\boldsymbol{k,j}} \cdot \boldsymbol{JPP}_{\boldsymbol{k,j-1}} + \boldsymbol{JPP}'_{\boldsymbol{k,j}}}{\boldsymbol{MS_j}} \tag{9}$$

$$\boldsymbol{PPT}_{\boldsymbol{k,j}} = \frac{\sum_{\boldsymbol{k\in M, j\in N}} \boldsymbol{Y}_{\boldsymbol{k,j}} \cdot \boldsymbol{JPT}_{\boldsymbol{k,j-1}} + \boldsymbol{JPT}'_{\boldsymbol{k,j}}}{\boldsymbol{MS_j}} \tag{10}$$

4 Computational study

4.1 Experiment design

The computational study is conducted to investigate the relationships between the number of AM machines and the APT as well as the total profit can be obtained under various market demand when considering the idle cost of each AM machine. A series of test problems are designed to demonstrate various on-demand AM production environments. Each test problem consists of different numbers of AM machines with the same specification and different numbers of part orders which arrived randomly during a specific time duration.

The specifications of the AM machines are given empirically as shown in Table 4, while the parameters of part orders are generated randomly with specific arrival time r_i, boundary dimensions ($h_i \times w_i \times l_i$), material volume v_i, and the due date d_i promised by the service provider. All the parts are assumed to arrive randomly within 30 days. The random ranges of parameters for the part orders used in this paper are shown in Table 5.

Table 4. Specifications of AM machines used for the experiment.

Parameters	Values
$H_k \times W_k \times L_k$, (cm^3)	32.5×25×25
VT_k, $(hour/cm^3)$	0.030864
HT_k, $(hour/cm)$	0.7
ST_k, $(hour)$	2
TC_k, (GBP/cm^3)	60
HC_k, $(GBP/hour)$	30
MC, (GBP/cm^3)	2
P_k, (GBP/cm^3)	6
IC_k, $(GBP/hour)$	0, 1.5, 5

Table 5. Parameters of part orders used for the experiment.

Parameters	Random Range	Example
r_i, (time moment in hours)	0~720	439
d_i, (time moment in hours)	$r_i + 336$	775
h_i, (cm)	2~32	20
w_i, (cm)	2~25	9
l_i, (cm)	2~25	10
v_i, (cm^3)	$h_i \times w_i \times l_i \times$ (0.3~0.8)	1132

Seven levels of the number of AM machines (1, 3, 5, 7, 10, 15, and 20) are considered for each size of test problem according to a different number of part orders (50, 150, and 300) to demonstrate various market demand. Particular, three levels of idle cost ($IC_k = 0, IC_k = 1.5\ and\ IC_k = 5.0$) are considered for each problem to investigate the influence of idle cost on the performance of a different number of AM machines. The proposed heuristic procedure was implemented in Python language, and all experiments were performed on a computer equipped with Intel® Core™ i7-7700 CPU @3.60GHz processors and 32 GB RAM.

4.2 Experiment results

According to the discovery in our previous work, the performance of each decision-making strategy set is affected by the changing of market demand where the best schedule result was generated by applying one of six decision-making strategy set but by one specific strategy set. Therefore, each test problem was solved by applying all the six decision-making strategies and the best schedule result of each problem is used for the investigation of the relationships between the number of machines and the market demand. Also, as the total profit equals APT multiply by the whole makespan, they are equivalent when used for analyzing the performance of the machines. The total profit generated by various number of AM machines ($IC_k = 5.0$) with different decision-making strategy sets under market demand of 150 part orders is shown in Table 6 for example. It can be seen that the best results were presented by different decision-making strategy set, and the maximum total profit increasing as the number of AM machines increasing from 1 to 15. However, the total profit is reduced from £349,288 to £326,480 when the number of AM machines increased from 15 to 20.

Table 6. The total profit generated by machines with different decision-making strategy.

	Total Profit (£)						
M	GPMS_ LPMS	GPMS_ LPPT	GPMS_ LFIFO	GPPT_ LPMS	GPPT_ LPPT	GPPT_ LFIFO	BEST RESULT
1	**50024**	49817	28616	50024	49817	28616	**50024**
3	**143223**	135149	114523	142608	135149	114523	**143223**
5	200793	198037	204107	200793	198037	**204895**	**204895**
7	205712	222114	**280841**	205712	228447	278032	**280841**

10	191303	219219	321565	191303	225552	**330428**	**330428**
15	167288	195924	347951	167288	202256	**349288**	**349288**
20	143274	172628	326414	143274	178961	**326480**	**326480**

To further investigate the changing of total profit with various number of AM machines, the maximum total profit generated by various number of AM machines with different decision-making strategy sets under market demands of 50, 150, and 300 part orders are compared and illustrated in Fig. 4.

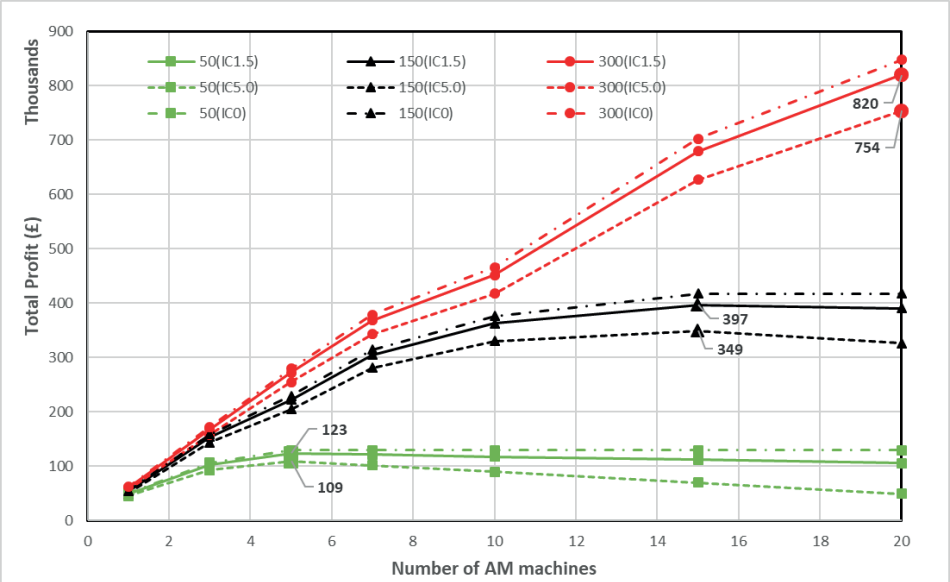

Fig. 4. Relationships between the numbers of AM machines and obtained total profit.

It can be seen that the total profit always lower when the value of IC_k higher for any size of market demand and the difference become bigger along with the growth of the number of AM machines. Under the market demand of 300 part orders, the total profit keep increasing along with the growth of the number of AM machines while the increasing speed is dropping slightly. However, for the market demand of 50 and 150 part orders, the maximum total profit is obtained at 5 and 17 AM machines respectively and then dropping along with the growth of the number of AM machines. It is interesting to note that, when the idle cost was not considered ($IC_k = 0$), the total profit remains unchanged when it reached a specific level for market demand of 50 and 150 part orders.

Based on the analyses of the experiment results, we can say that a proper number of AM machines should be invested to match with a specific level of market demand particular for service providers who need to pay a high site use and administrative fees. The approach proposed in this paper can be used for the decision making on the number of AM machines to be invested through simulation with predicated market demand.

However, the service price as well as the promised due date is assumed to be fixed for the experiment conducted in this research, which means the competitiveness of the service provider is restricted. While in an online 3D printing service platform where exist multiple service providers, a service provider can improve their competitiveness by offering a lower price and/or shorter due date to attract more part orders.

5 Conclusions and future research

This study introduced the dynamic OAS problem in on-demand production with multiple PBF systems by considering the idle cost of each machine. The mathematic model, as well as the heuristic procedure, was retrofitted based on our previous work for the investigation of the relationships between the number of machines and the total profit can be obtained under various market demand levels. A computational experiment was designed and conducted which consists of a series of test problems by considering different market demand levels, number of AM machines, and idle cost for each AM machine. The experiment results indicated that the total profit is increasing along with the growth of the number of AM machines when the market demand is big enough. However, when the market demand relative smaller, the maximum total profit obtained at a specific number of AM machines and then dropping along with the growth of the number of AM machines. The proposed decision-making strategy-based heuristic approach has been demonstrated in our previous work [11] that it is practical to solve the dynamic OAS problem in on-demand production with PBF systems, and also it can be used as an analytic tool to find out proper promised due date to maximize profit. By considering idle cost in this paper, the proposed heuristic approach can be further considered as a tool for the decision making on the number of AM machines to be invested through simulation with the predicated market demand.

As an emerging disruptive manufacturing technology, the applications of PBF technologies has been increased substantially in various industries during the past years, and considerable research has been carried out from scientific and technological challenges to business models innovations as well as industrial application issues[5,6,15-20]. However, the study on production planning particular OAS problems in on-demand production with PBF systems is just catching up. Most recently, the dynamic OAS problems in on-demand production with PBF systems have been discussed in our reported works and a decision-making strategy based heuristic approach was proposed for the environment with individual service provider[11] as well as with multiple competitive service providers[12,14]. The proposed heuristic approach has been validated through comprehensive experimental study where promising schedule results can be obtained by applying properly decision-making strategies. However, further investigations need to be carried out for practical applications. Firstly, the proposed mathematic model, as well as the cost structures, can be further extended by considering true shape 2D/3D nesting algorithms to cover more industrial AM processes such as Selective Laser Sintering (SLS) and binder jetting (ASTM:F2790-12a). Secondly, advanced methodologies based on machine learning and/or bio-inspired algorithms are expected for the development of optimal decision-making strategies. Furthermore, the competitive

mechanism among service providers need to be investigated and a high-efficiency heuristic approach needs to be developed to support the generation of competitive offers with flexible price and due date.

Abstract. The combined Inventory Routing Problem and Crew Scheduling problems are studied in this work based on a mathematical formulation for the combined problems. Given the complexity of the mathematical models proposed a decomposition approach composed by three different phases is proposed: Inventory – Routing and Crew allocation, therefore the global problem is solved iteratively by solving first the Inventory sub-problem, these results are used as an input for the Routing sub-problem and it is solved, then these solutions are used as an input for the Crew allocation sub-problem and then solved. We have used an optimization software that allow us to solve iteratively these sub-problems and get the optimal solution for each phase of the decomposition. The general assumptions of the decomposition are presented along with some preliminary results of our proposal. To get the results we have adapted the well-known instances of the classic Inventory Routing Problem adding new elements such us drivers, schedules, hours per day, among others.

Keywords: Inventory Routing Problem, Crew Scheduling Problem, Decomposition Approach.

1 Introduction

Decisions of inventory and routing are interrelated in distribution networks and in supply chains, for example in [1] an application the combination of transportation and inventory management in a gas company is presented. In this sense, several computational and real life applications have been developed for study these combined problems [2]–[6]. An exact approach for this problem is developed in [7] where authors proposed an exact model using the branch and cut strategy including the evaluation of two inventory strategies. On the other hand, shift and crew scheduling also affects the distribution planning process. The work presented in [8] one of the first works that combine these three different elements into one model.

In this research we propose an extension of the classical Inventory Routing Problem by including the crew scheduling problem considering breaks in the planning process and propose a decomposition strategy.

2 Problem Description

The problem is formulated by joining two different well known problems, the first one the classic Inventory Routing Problem which is defined over a graph G=(V,A) where $V = \{v_1, \dots, v_{n+1}\}$ corresponds to the set of nodes where the first node represents the central depot or warehouse and the rest of the nodes corresponds to the customers. On the other hand the set of arcs $A = \{(i,j) \mid i,j \in V, i \neq j\}$ that creates the distribution routes between the customers and the depot. The supplier from a central depot must satisfy the demand of a subset of customers $V_p = V \setminus \{1\}$, the demand is assumed to be deterministic and varies for each period time where in each period time it can be chosen the shift where the product can be delivered. Also, there is a set of drivers that must be assigned to vehicles and shifts to distribute the product over the customers.

3 Solution Approach and Some Results

The proposed method consists in solving exactly the sub-problems proposed joining the results obtained with the next phase of the decomposition. In this sense, the proposed decomposition is presented in Algorithm 1.

Algorithm 1. Decomposition proposed.

Decomposition Approach	
1:	Define planning horizon $\lvert\mathcal{T}'\rvert$
2:	for t in $\mathcal{T}'$, do
3:	Solve inventory_model()→ s_1
4:	$Isolit \leftarrow Iit - SOit \ \forall i \in \mathcal{V}; t \in \mathcal{T}'$
5:	$qsolikft \leftarrow qikft \ \forall i \in \mathcal{V}; k \in \mathcal{K}; f \in \mathcal{F}; t \in \mathcal{T}'$
6:	$ysolikft \leftarrow yikft \ \forall i \in \mathcal{V}; k \in \mathcal{K}; f \in \mathcal{F}; t \in \mathcal{T}'$
7:	If s_1 is optimal or feasible then
8:	Solve routing_model()→ s_2
9:	$xsolijkft \leftarrow xijkft \ \forall i \in \mathcal{V}; j \in \mathcal{V}; k \in \mathcal{K}; f \in \mathcal{F}; t \in \mathcal{T}'$
10:	$esolikft \leftarrow eikft \ \forall i \in \mathcal{V}; k \in \mathcal{K}; f \in \mathcal{F}; t \in \mathcal{T}'$
11:	$wsolkft \leftarrow wkft \ \forall k \in \mathcal{K}; f \in \mathcal{F}; t \in \mathcal{T}'$
12:	Else: Break
13:	If s_2 is optimal or feasible then
14:	Solve personnel_model()→ s_3
15:	$gsoldhorizonte \leftarrow gdhorizonte \ \forall d \in \mathcal{D}; t \in \mathcal{T}'$
16:	$Bi \leftarrow Isolit - \bar{X}i + dit$
17:	Else: Break
18:	End for

The Algorithm 1 is composed by the solution of three different sub-problems: The *inventory_model(),* The *routing_model()* and The *personnel_model()*. The *inventory_model()* takes as an input the planning horizon and solves a mixed integer model that minimize the total inventory costs considering constraints related to inventory levels at depot and the customers, the bounds of the inventory levels only for the customers and it considers the capacities of vehicles. In the *routing_model()* a vehicle routing problem with time windows (VRPTW) is solved aiming to minimize the traveling costs including the time windows penalizations, the constraints are related to the flow balance constraints, capacities, time windows and sub-tour eliminations and the definition of the shifts (beginning-end and break). Finally, the *personnel_model()* solves a mixed integer model to allocate drivers to shifts aiming to minimize the personnel allocation costs with constraints related to allocation of drivers in vehicles and logical constraints of vehicles with shifts and drivers.

In order to test the proposed approach, the instances proposed in [2], [7] have been adapted considering the different elements added such as drivers, time windows and shifts with breaks. The results are presented in two separate tables, Table 1 with the results of 5 customers and Table 2 with the results of 10 customers. The metrics used to analyze the results are the routing costs, the average of vehicles used per period time, the average occupation of vehicles, the crew costs, the average cost per driver and the average occupation of drivers. The model were solved using Xpress-MP.

Table 2. Results with 5 customers.

Abstract. En este trabajo se propone un algoritmo evolutivo para resolver de manera combinada el Order Batching Problem y el Order Picking Problem. Este problema combinado consiste en seleccionar y recoger en lotes varios artículos de pedidos de distintos clientes de forma simultánea desde un área de almacenamiento y dado un plazo para la finalización del armado de cada pedido conforme a un plan de distribución. Se busca determinar el plan que minimiza el costo total del proceso de picking, el que será directamente proporcional al tiempo de desplazamiento en el área de almacenamiento, al tiempo para recoger cada artículo y descargarlo en el área de despacho y a la puntualidad en el armado de cada pedido, en el sentido de que la anticipación o la demora acarreará costos por ineficiencia en el uso del espacio o por incumplimientos del plan de distribución. Del análisis de los resultados alcanzados, al compararlos con otros resultados extraídos de la literatura, se observa un buen desempeño del algoritmo propuesto en este trabajo.

Keywords: Order Batching, Order Picking, Algoritmo Evolutivo.

1 Introducción

La optimización de procesos dentro de un centro de distribución es un factor crítico para el desempeño operativo de la logística interna y externa de la empresa. Estos procesos operativos están relacionados a los movimientos de mercaderías dentro de los centros de distribución, como el de recepción, ubicación, almacenamiento, selección y

recolección de pedidos, clasificación y despacho [1] [2]. El almacenamiento, hace referencia a la guarda física de los artículos a la espera de un pedido. La selección y recolección de estos artículos es el proceso principal en la mayoría de los depósitos. Consiste en tomar desde las ubicaciones de almacenamiento correspondientes, la cantidad correcta de los artículos correctos en base a lo requerido por los clientes en sus pedidos, para transportarlos hacia la zona de preparación de los pedidos [3]. La clasificación de los pedidos seleccionados y recolectados consiste en la reagrupación de las unidades de cada lote en los pedidos individuales de cada cliente una vez que se completa el proceso de picking [4] [5]. En la mayoría de los casos este proceso incluye las actividades de marcado y etiquetado, de embalaje y agrupamiento en una unidad indivisible de carga. El despacho es el proceso que involucra la verificación de cada unidad de carga chequeando que los pedidos estén completos, la elaboración de los documentos necesarios para poder despachar la mercadería y finalmente la carga de la misma al medio de transporte. El presente trabajo se enfoca en la optimización del proceso de selección y recolección de pedidos.

2 Descripción del problema y revisión de la literatura

Respecto a los mencionados procesos operativos relacionados al movimiento de mercaderías dentro de los depósitos, se identifican claramente tres problemas. El primero de ellos, es la asignación de los artículos ingresados a diferentes posiciones de almacenamiento. El segundo, es el agrupamiento de artículos de pedidos de clientes en lotes para su recolección. Y el tercero, es la programación de la secuencia de recolección de los artículos realizada por los equipos de picking y el traslado al área de despacho [6] [7] [8]. En este trabajo nos enfocamos en el tratamiento integrado de estos dos últimos problemas, dado que son críticos para la eficiencia de las operaciones del depósito e involucran la mayor parte de los costos de las operaciones del depósito, al comprender actividades intensivas en mano de obra [9] [10]. Para entender este problema primero debemos describir con mayor detalle el proceso de selección y recolección de los artículos. Este proceso comienza con el ingreso de una orden de preparación de una determinada cantidad de pedidos realizados por distintos clientes, en la que se detalla para cada pedido las cantidades y especificaciones de distintos artículos disponibles en el área de almacenamiento, y en la que se define la fecha o momento en el que debe estar disponible cada pedido en el área de despacho. Este momento está definido en base al programa de distribución y el tiempo requerido en el proceso de clasificación y despacho. Los artículos deben ser recogidos de las posiciones de almacenamiento en el menor tiempo posible, para lo que cada equipo de picking, debe visitar una secuencia de posiciones de almacenamiento con el fin de tomar los artículos solicitados. Al finalizar esta operación, se obtiene el tiempo de procesamiento de la orden y de cada uno de los pedidos. El problema integrado consiste en determinar el plan que minimiza el costo operativo del proceso de picking, esto es, el costo de seleccionar y recoger en lotes varios artículos de pedidos de distintos clientes de forma simultánea desde un área de almacenamiento determinada dado un plazo para la finalización del armado de cada

pedido, donde cada pedido está conformado por distintas cantidades de diferentes artículos y cada lote está conformado por una variedad de artículos de diferentes pedidos [11] [12] [13]. Por un lado, si se excediera el momento en que finaliza el armado del pedido respecto al momento en que dicho pedido debía estar listo, se incurriría en costos por incumplimientos del programa de distribución. Y, por otro lado, si dicho momento se anticipara se incurriría en un costo por la utilización ineficiente del área de despacho, al ocuparse con pedidos que todavía no deben ser despachados obstaculizando los flujos dentro del área aumentando sus tiempos de procesamiento [11]. Formalmente, el problema integrado está compuesto por el Order Batching Problem (OBP) y el Order Picking Problem (OPP) [14] [15] [16]. El OBP consiste en encontrar la cantidad y el tamaño óptimo de los lotes de artículos, para que cada lote sea recogido por un equipo de picking [13]. Para esto se debe considerar la capacidad del equipo de picking y el momento requerido en que debe estar cada artículo en el área de despacho para la finalización del armado de cada pedido [17] [18] [19]. El OPP consiste en identificar secuencias óptimas de visitas de las posiciones de almacenamiento en las que se encuentran cada uno de los artículos incluidos en un lote determinado [20] [21] [22]. En adelante se identifica este problema integrado como OBP+OPP. En [2] se realiza una revisión de la literatura sobre el OBP y el OPP. En [1] [21] [23] se presenta una revisión de heurísticas para el OPP. En [8] se presentan dos formas de resolución al OPP, mediante Ant Colony Optimization y mediante Iterated Local Search. En [15] se presentan otras meta-heurísticas aplicadas a los problemas de ruteo subyacentes. En [4], se utiliza un enfoque basado en el clustering para resolver el OBP teniendo en cuenta patrones de demanda en lugar de la distancia recorrida en cada secuencia de visitas. En [7] se propusieron varias heurísticas para el OBP. Luego, en [13] se propuso un modelo de programación entera para el OBP donde las distancias de cada secuencia de visita son estimadas y el problema se resuelve con una heurística basada en lógica difusa. En [11] se utiliza un algoritmo genético múltiple para resolver el OBP+OPP. Este trabajo es novedoso por la utilización de ventanas temporales flexibles para el tiempo de entrega de cada pedido. En el presente trabajo se sigue la metodología utilizada en esta última publicación, pero utilizando para la resolución del problema un algoritmo evolutivo con un cromosoma específico que facilita la utilización de diferentes números de lotes. Mediante este algoritmo se busca obtener mejoras en el desempeño comparando los resultados obtenidos sobre las instancias y configuración del lay-out propuestos en la publicación mencionada.

3 Definición de parámetros y variables

$\mathcal{P} = \{1, \dots, nArt\}$ es el conjunto de artículos, hay $nArt$ tipos de artículos diferentes y cada uno de estos tipos de artículos tiene un peso unitario determinado. El conjunto de pesos unitarios de los $nArt$ tipos de artículos se representa mediante $\mathcal{W} = \{w_1, \dots, w_p, \dots, w_{nArt}\}$. $\mathcal{P}_i$ es el subconjunto de artículos pedidos por el cliente i, es decir $\mathcal{P}_i \supset \mathcal{P}$. Además se supone que cada cliente realiza un solo pedido de varios artículos diferentes con distintas cantidades de cada uno de ellos, por lo que la cantidad de clientes, nC, es igual a la cantidad de pedidos, $nPed$, quedando el conjunto de

clientes determinado por $\mathcal{I} = \{1, \dots, i, \dots, nC\}$. Cada pedido tiene un plazo determinado para finalizar con su armado, los plazos de finalización de todos los pedidos están representados en el conjunto $\mathcal{T} = \{t_1, \dots, t_{\mathrm{i}}, \dots, t_{nPed}\}$. $\mathcal{P}_{\mathrm{r}}$ es el subconjunto de artículos diferentes presentes en el lote r. Es decir $\mathcal{P}_{\mathrm{r}} \supset \mathcal{P}$. Los artículos en $\mathcal{P}_{\mathrm{r}}$ pueden provenir de pedidos de diferentes clientes o no. $\mathcal{L} = \{\ell_0, \ell_1, \dots, \ell_{\mathrm{p}}, \dots, \ell_{\mathrm{nArt}}\}$ son las posiciones de almacenamiento de cada uno de los tipos de artículos, más ℓ_0 que es la localización del área de despacho dentro del almacén. Por ejemplo, para el artículo $p \in \mathcal{P}$, la posición de almacenamiento ℓ_{p} está dada por sus coordenadas dentro del depósito, es decir, $\ell_{\mathrm{p}} = (x_p, y_p)$. $\mathcal{R} = \{1, .., \mathrm{r}, \dots, |\mathcal{R}|\}$ es el conjunto de lotes a recoger por los operadores de los equipos de picking. Donde $|\mathcal{R}|$ es la cantidad de lotes a recoger. $\mathcal{S}_{\mathrm{r}} = \langle \mathrm{s}_1, \dots, \mathrm{s}_{\mathrm{u}}, \dots, \mathrm{s}_{|\mathcal{S}_{\mathrm{r}}|} \rangle$ es la ruta o sucesión de posiciones de almacenamiento a visitar en el lote r. Es decir, $r \in \mathcal{R}$ y $\mathcal{S}_{\mathrm{r}} \supset \mathcal{L}$. Y donde, s_u es la u-ésima posición de almacenamiento a visitar en el lote r y $|\mathcal{S}_{\mathrm{r}}|$ es la cantidad de artículos diferentes del lote r. $\mathcal{Q}$ es el conjunto de las cantidades de cada artículos pedidos por todos los clientes, donde, $q_{i,p} \in \mathcal{Q}$ es la cantidad total pedida por el cliente i del artículo p. Luego $\mathcal{Q}_i = \sum_{p \in \mathcal{P}_i} q_{i,p}$ es la cantidad total de artículos solicitada por el cliente i. $\mathcal{Q}_p = \sum_{i \in \mathcal{I}} q_{i,p}$ es la cantidad pedida por todos los clientes del artículo p. Y $\mathcal{Q}_{\mathrm{r}} \supset \mathcal{Q}$ es el conjunto de cantidades de distintos artículos agrupados en el lote r. $\mathcal{Q}_r = \{q_1, \dots, q_p, \dots, q_{|\mathcal{S}_r|}\}$. $\mathcal{K} = \{1, \dots, |\mathcal{K}|\}$ es el conjunto de equipos de picking con capacidad Cap. Luego, el problema integrado OBP+OPP, se define en un grafo no dirigido $\mathcal{G} = (\mathcal{V}, \mathcal{A})$, donde: $\mathcal{V}$ es el conjunto de nodos que representan todas las posiciones de almacenamiento (lugares físicos) de cada uno de los artículos $p \in \mathcal{P}$, más dos copias (0 y $n+1$) del nodo inicial (ubicación del área de despacho). $\mathcal{A}$ representa el conjunto de todos los arcos factibles entre todos los nodos del conjunto $\mathcal{V}$. Cada $\mathrm{arco}(h, l) \in \mathcal{A}$ tiene asociado un tiempo t_{hl} dado por la distancia entre los nodos h y l dividida por la velocidad del equipo de picking v (esto es $t_{hl} = D_{h,l}/v$) y un costo operativo por unidad de tiempo ς. Luego, t_{pick} es el tiempo medio para recoger un artículo, una vez que el operador ha llegado al punto de almacenamiento de un artículo determinado. $\mathcal{Q}_{\mathrm{i}}$ representa la cantidad total de artículos pedidos por el cliente i, donde $\mathcal{Q}_i = \sum_{p \in \mathcal{P}} q_{i,p}$. Esto significa que la cantidad total de artículos pedidos por el cliente i, q_i, está formada por la suma de las cantidades solicitadas, en ese pedido, de cada uno de los h artículos solicitados por el cliente i. $x_{hlkr} = 1$ si y solo si el artículo h es recogido inmediatamente antes del artículo l por el equipo de picking k en la secuencia del lote r, donde $h, l \in \mathcal{V}$, $k \in \mathcal{K}$ y $r \in \mathcal{R}$. Es decir, es igual a 1 si el vehículo k al recoger el lote r atraviesa el $\mathrm{arco}(h, l)$. $y_{hkr} = 1$ si y solo si el equipo de picking k recoge el artículo h en el lote r, donde $h \in \mathcal{V}$, $k \in \mathcal{K}$ y $r \in \mathcal{R}$. El modelo para el OBP+OPP es el siguiente [3] [11]:

$$\min C_{Total}: \left[\frac{\sum_{h \in \mathcal{V}} \sum_{l \in \mathcal{V}} D_{h,l} \cdot \sum_{k \in \mathcal{K}} \sum_{r \in \mathcal{R}} x_{hlkr}}{v} + \sum_{\substack{p \in \mathcal{P} \\ q \in \mathcal{Q}}} q_p \cdot t_{pick} \right] \cdot \varsigma + \sum_{i \in \mathcal{I}} (\alpha \cdot E_i + \beta \cdot T_i) \quad (1)$$

s.a.:

$$\sum_{p\in\mathcal{P}_r}(q_p \cdot w_p) \cdot y_{pkr} \leq Cap,\ \forall k \in \mathcal{K}, r \in \mathcal{R} \quad (2)$$

$$\sum_{r\in\mathcal{R}} y_{hkr} = 1,\ \forall h \in \mathcal{P}, \forall k \in \mathcal{K} \quad (3)$$

$$\sum_{k\in\mathcal{K}} y_{hkr} = |\mathcal{K}|,\ \forall h \in \{0, n+1\}, r \in \mathcal{R} \quad (4)$$

$$\sum_{h\in\mathcal{V}} x_{hlkr} = y_{lkr},\ \forall l \in \mathcal{V} \setminus \{0\}, k \in \mathcal{K}, r \in \mathcal{R} \quad (5)$$

$$\sum_{l\in\mathcal{V}} x_{hlkr} = y_{hkr},\ \forall h \in \mathcal{V} \setminus \{n+1\}, k \in \mathcal{K}, r \in \mathcal{R} \quad (6)$$

$$\sum_{i\in\mathcal{I}} \sum_{k\in\mathcal{K}} \sum_{r\in\mathcal{R}} q_{i,p} \cdot y_{pkr} = Q_p,\ \forall p \in \mathcal{P} \quad (7)$$

$$\sum_{p\in\mathcal{P}} \sum_{k\in\mathcal{K}} \sum_{r\in\mathcal{R}} q_{i,p} \cdot y_{pkr} = Q_i,\ \forall i \in \mathcal{I} \quad (8)$$

$$x_{hlkr} \in \{0,1\},\ \forall h, l \in \mathcal{V}, k \in \mathcal{K}, r \in \mathcal{R} \quad (9)$$

$$y_{hkr} \in \{0,1\},\ \forall h \in \mathcal{V}, k \in \mathcal{K}, r \in \mathcal{R} \quad (10)$$

La función objetivo (1) representa el costo total expresado en unidades monetarias por unidad de tiempo consumida en la recolección de pedidos en lotes, más una penalización por incumplimiento del plazo para finalizar el armado del pedido. El primer término de esta función, considera el tiempo de desplazamiento desde el área de preparación hasta y entre las posiciones de almacenamiento, más el tiempo de recolección, que es el tiempo requerido para recoger cada artículo una vez que se ha llegado a la posición de almacenamiento. El tiempo de desplazamiento surge del cociente entre la distancia recorrida y la velocidad promedio de desplazamiento del equipo de picking. Respecto a la función de penalización por anticipación o demora en el cumplimiento del plazo para finalizar el armado de cada pedido, α es la penalización por unidad de tiempo en que se anticipa el armado de un pedido. β es la penalización por unidad de tiempo en que se retrasa el armado de un pedido. E_i es la cantidad de tiempo en que se anticipa al plazo el armado del pedido i. Y T_i es la cantidad de tiempo en que se retrasa el armado del pedido i. Donde $E_i = max\{0, t_i - c_i\}$ y $T_i = max\{0, c_i - t_i\}$. Y siendo c_i el tiempo de finalización efectiva para el pedido i, que se define como el tiempo en el que todos los artículos del pedido i son recogidos y devueltos al área de despacho. El conjunto de restricciones (2) no permite que el peso de los artículos de un lote determinado exceda la capacidad de cada equipo de picking. El conjunto de restricciones (3) indica que cada posición de almacenamiento no sea visitada más de una vez en cada lote r. El conjunto de restricciones (4) asegura que todos los equipos de picking salgan y regresen al área de preparación para despacho. El conjunto de restricciones (5) y (6) preservan el flujo. Si el equipo de picking k recoge el artículo l en el lote r, antes tiene que haber recogido al artículo h. Y si el equipo de picking k recoge el artículo h en el lote r, antes tiene que haber recogido al artículo l. La restricción (7) indica que se cumpla con la cantidad pedida por todos los clientes del artículo p. La restricción (8) indica

que se cumpla con la cantidad pedida de todos los artículos, por el cliente i. Las restricciones (9) y (10) imponen las condiciones sobre los valores de las variables.

4 Método de resolución

La teoría computacional clasifica a estos problemas con una complejidad NP-Hard. Es decir, que se pueden resolver de forma exacta solo en instancias muy pequeñas. Dada la intratabilidad de este problema, se requiere de algoritmos no deterministas para resolverlo en tiempos polinomiales. Por esta razón se propone un algoritmo evolutivo para resolver este problema. Se utiliza una representación del tipo permutación de enteros, muy común en problemas de optimización combinatoria como este. Se usa una representación con un cromosoma compuesto por dos genomas. Para explicar la representación veamos mediante un ejemplo muy simple, cómo se codifica una solución a partir de tres pedidos de entre los que se identifican solicitudes de cuatro artículos diferentes. En la Tabla 1, se muestra la información respecto a los pedidos ingresados. Puede verse que el pedido 1 está constituido por 3 artículos (una unidad del tipo A y dos unidades del tipo C), el pedido 2 por 5 artículos (una unidad de A, una de B, dos de C y una de D) y el pedido 3 por 4 artículos (dos unidades de B y dos de D).

Tabla 1. Ejemplo para el OBP+OPP

Pedidos	**Artículos**				**Total**
	A	**B**	**C**	**D**	
1	1	0	2	0	3
2	1	1	2	1	5
3	0	2	0	2	4
Total	2	3	4	3	12

Para codificar esta información, la ordenamos en dos filas, una para los artículos (y se identifica el pedido al que corresponde cada artículo) y otra para asociar un número entero a cada uno de los artículos (Tabla 2).

Tabla 2. Codificación

Artículos (Pedido al que pertenece)											
A(1)	A(2)	B(2)	B(3)	B(3)	C(1)	C(1)	C(2)	C(2)	D(2)	D(3)	D(3)
↑	↑	↑	↑	↑	↑	↑	↑	↑	↑	↑	↑
1	2	3	4	5	6	7	8	9	10	11	12

Luego, se diseña un cromosoma con dos genomas (Tabla 3) que tiene en cuenta la codificación de la Tabla 2.

Cromosoma: {[G1] [G2]}

Genomas:

[G1]: Secuencia en que se recogerán los artículos en el almacén.

[G2]: Secuencia de posiciones en el [G1] de finalización de cada lote.

Dimensiones:

[G1]: Número total de artículos $\sum_{i\in\mathcal{I}} Q_i$.

[G2]: Número total de artículos $\sum_{i\in\mathcal{I}} Q_i$ (el límite corresponde a lotes de un solo artículo).

Tabla 3. Cromosoma = Genoma 1 + Genoma 2

Genoma 1												
Posiciones →	1	2	3	4	5	6	7	8	9	10	11	12
[G1] →	6	7	9	10	11	1	3	2	12	4	8	5
	lote 1					lote 2		lote 3				
Genoma 2												
[G2] →	5	7	12	-	-	-	-	-	-	-	-	-

La secuencia en que se recogerán los artículos correspondientes a cada lote es la siguiente, lote 1: {6→7→9→10→11}, lote 2: {1→3} y lote 3: {2→12→4→8→5}. Esto indica, por ejemplo, que para el lote 2, el equipo de picking debe ir a la posición de almacenamiento del artículo 1 (A(1)), luego se debe ir a la posición de almacenamiento del artículo 3 (B(2)) y finalmente ir al área de despacho y colocar cada artículo en el lugar del área de almacenamiento donde se están armando los pedidos. En la figura 1 se muestran los recorridos que realizarán los equipos de picking. Este tipo de representación permite lograr mayores niveles de eficiencia en este tipo de problemas y da la posibilidad de incorporar de manera directa conocimiento específico del problema, lo que da mayor flexibilidad a la representación y facilita la consideración de restricciones en el espacio de búsqueda. Por otro lado, la factibilidad de los individuos respecto a los conjuntos de restricciones (2) - (8) están garantizados por la representación. En la inicialización, se busca la mayor variedad posible generando la población inicial de forma aleatoria y se utiliza un criterio de terminación enfocado al costo, que limita el número máximo de iteraciones. El proceso de búsqueda es dirigido mediante el criterio de selección favoreciendo los individuos más aptos. Para ello se utiliza la técnica de selección por torneo en la que cada individuo se toma eligiendo el mejor de un conjunto de *k* individuos tomados al azar de la población actual [24]. Esto se repite iterativamente hasta completar la muestra. Los operadores genéticos son aplicados al Genoma 1. Se utiliza un operador de cruce Edge Recombination Operator [25] y un operador de mutación de inserción [26]. El Genoma 2 se completa de acuerdo a la capacidad del equipo de Picking. El seudo-código del algoritmo propuesto se presenta en la figura 2.

5 Experimento computacional

Con el propósito de evaluar la calidad de las soluciones y el rendimiento del algoritmo propuesto se utilizaron las instancias propuestas en [11]. Se resolvieron tres instancias. Una instancia mediana (DS1/M1), una grande (DS2/M1) y una muy grande (DS3/M1) (Tabla 4).

Tabla 4. Características de las instancias [11]

	DS1/M1	**DS2/M1**	**DS3/M1**
Número de pedidos	40	80	200
Número de artículos diferentes	80	160	300
Peso total medio (kg.)	13.704	37.152	158.784
Capacidad del equipo de picking (kg.)	10.000	10.000	20.000

Para las instancias, se suponen las siguientes distribuciones de probabilidad. La cantidad del artículo p en el pedido del cliente i sigue una distribución uniforme entre 1 y 10, es decir, $q_{i,p} \sim U(1, \dots, 10)$. El número de artículos diferentes en el pedido de un cliente i sigue una distribución normal, con media 10 y desviación estándar 5, es decir $|\mathcal{P}_i| \sim N(10,5)$. El plazo en el que debe estar finalizado el armado de un pedido i, sigue una distribución uniforme, estos momentos se consideran discretizados en segundos y están entre las 10:00 am y las 18:00 pm, esto es, $t_i \sim U(36000, \dots, 64800)$. El peso unitario de cada artículo p, sigue una distribución uniforme entre 8 y 24 kg., es decir, $w_p \sim U(8, \dots, 24)$. Respecto a los parámetros de los equipos de picking, se supone una velocidad promedio de desplazamiento de $v = 2\ m/s$, un tiempo medio para la recolección de cada artículo de $t_{pick} = 15$ seg., un costo de desplazamiento por unidad de tiempo de $\varsigma = 0{,}05$ u.m. y una capacidad de carga (Cap) que depende del tipo de instancia que se esté considerando. En cuanto a los parámetros de la función objetivo, se considera una penalización por unidad de tiempo de anticipación en el plazo para el armado de un pedido de $\alpha = 0.5$ y una penalización por unidad de tiempo de demora en el cumplimiento del plazo para la finalización en el armado de un pedido de $\beta = 1$. Se utilizará la estrategia para acotar el espacio de búsqueda propuesta en [11] con el objetivo de que el desempeño del algoritmo sea comparable con los resultados obtenidos en esta publicación. Esto es, determinar un límite inferior, $|\mathcal{R}|_{min}$, y un límite superior, $|\mathcal{R}|_{max}$, para la cantidad de lotes en los que se agrupan los artículos a recoger, es decir, $|\mathcal{R}|_{max} \leq |\mathcal{R}| \leq |\mathcal{R}|_{min}$. Estos límites están dados por $|\mathcal{R}|_{min} = (\varphi_1 \cdot \sum_{p \in \mathcal{P}} w_p)/Cap$ y $|\mathcal{R}|_{max} = (\varphi_2 \cdot \sum_{p \in \mathcal{P}} w_p)/Cap$. Donde φ_1 y φ_2 son constantes decididas por los usuarios, y $\varphi_2 \geq \varphi_1$. El número máximo de iteraciones se fijó 500, el tamaño de la población en 150, el tamaño del torneo en 2, los parámetros de los límites del espacio de búsqueda $\varphi_1 = 2$ y $\varphi_2 = 4$, la probabilidad de cruce en 0.9, la probabilidad de mutación 0.15, la cantidad de individuos que pertenecen a la elite es el 5% de la población. Se utilizará una PC con un procesador Intel Core i7 3.00 GHz y 8 GB de RAM.

6 Resultados

En esta sección se presentan los resultados obtenidos con el algoritmo propuesto al resolver las instancias DS1/M1, DS2/M1 y DS3/M1. Los mismos se compararon con los resultados extraídos de [11] (Tabla 5, D_{Total}: Distancia total (metros); n_{Lot}: Número óptimo de lotes (cantidad); $D_{Promedio}$: Distancia promedio (metros); D_{σ}: Desvío estándar (metros); T_{Demora}: Tiempo de demora en el armado de los pedidos (segundos); C_{Total}: Costo total (unidades monetarias); $T_{CPU\ promedio}$: Tiempo de corrida en CPU promedio (segundos). Se realizaron 30 corridas para cada una de las instancias.

Tabla 5. Resultados

	Resultados extraídos de [11]			**Algoritmo Evolutivo**		
	DS1/M1	**DS2/M1**	**DS3/M1**	**DS1/M1**	**DS2/M1**	**DS3/M1**
D_{Total}	1304.00	3569.00	16945.00	1266.00	3215.00	14548.00
n_{Lot}	8.00	11.00	27.00	8.00	12.00	27.00
D_{Media}	163.00	324.46	627.59	158.25	267.91	538.81
D_{σ}	3.70	25.17	18.69	2.90	23.41	21.75
T_{Demora}	1181.00	4704.00	15481.00	1158.70	4801.91	15621.31
C_{Total}	1092.60	3104.83	9207.13	1090.78	2961.89	8898.01
$T_{CPU\ promedio}$	753.60	2629.90	5785.50	605.70	2121.90	4474.20

La D_{Total} mejora en todas las instancias (DS1/M1, DS2/M1 y DS3/M1, 2.91%, 9.92% y 14.15%, respectivamente). Para las instancias DS1/M1 y DS3/M1, el n_{Lot} fue el mismo que en el caso de los resultados extraídos de [11], mientras que en la instancia DS2/M1 el n_{Lot} fue mayor. Para la instancia DS1/M1, el T_{Demora} mejora en un 1.89%, mientras que en las instancias DS2/M1 y DS3/M1 empeora en 2.08% y 0.91% respectivamente. Finalmente, el $T_{CPU\ promedio}$ en todas las instancias fue menor. En resumen, en la figura 3, se muestran las mejoras porcentuales obtenidas con el algoritmo propuesto en este trabajo con respecto a los resultados extraídos de [11].

7 Conclusiones

En este trabajo se presentó un algoritmo evolutivo para resolver de manera combinada el Order Batching Problem y el Order Picking Problem. El algoritmo propuesto para resolver el problema, presentó un novedoso criterio de representación con dos genomas, que permite la incorporación directa de conocimiento específico del problema, dando mayor flexibilidad y facilitando la consideración de restricciones en el espacio de búsqueda. El algoritmo fue testeado en instancias simuladas de distintos tamaños. Se observó que el algoritmo propuesto mejoró los resultados extraídos de [11]. A partir de este trabajo, se presenta como línea futura de investigación, la consideración de este problema bajo una plataforma cross-dock y se le dará un abordaje multi-objetivo.

Resumen. La gestión de la recolección de Residuos Sólidos Urbanos es una tarea compleja que deben enfrentar los gobiernos locales, consumiendo gran parte de su presupuesto. La utilización de herramientas computacionales que sirvan de apoyo a la toma de decisiones puede contribuir a mejorar la eficiencia del sistema y disminuir los costos asociados. En el presente trabajo se propone un algoritmo de recocido simulado para abordar el problema del diseño de las rutas de vehículos de recolección de residuos. El algoritmo propuesto es comparado contra otros dos algoritmos metaheurísticos: un algoritmo *Large Neighborhood Search* (LNS) de la literatura y un algoritmo genético estándar. La evaluación se realiza sobre instancias reales de la ciudad de Bahía Blanca y sobre *benchmarks* de la literatura. El algoritmo propuesto fue capaz de resolver todas las instancias planteadas teniendo un desempeño similar al LNS, mientras que el algoritmo genético estándar evidenció peores resultados.

Keywords: Residuos Sólidos Urbanos, Ruteo de Vehículos, Recocido Simulado.

1 Introducción

La generación de residuos sólidos urbanos (RSU) es una consecuencia inalienable del desarrollo de las ciudades modernas. Asimismo, su correcta gestión es uno de los elementos claves para el desarrollo sustentable de una ciudad [1]. Las etapas en la cadena logística inversa de los RSU son diversas. Según [2] pueden clasificarse en generación de residuos; manejo, separación, acumulación y procesamiento de residuos en origen; prosiguiendo la recolección; transferencia y transporte; separación, procesamiento y transformación de residuos sólidos; y disposición final. En dichas etapas existe una gran cantidad de decisiones que deben tomarse. Por este motivo, proponer herramientas informáticas que permitan asistir a los agentes tomadores de decisiones puede colaborar en un uso más eficiente de los recursos.

El presente trabajo se enfoca en la etapa de recolección; transferencia y transporte de residuos. Particularmente, se propone un algoritmo metaheurístico basado en recocido simulado para resolver este problema. El algoritmo propuesto es comparado contra otros algoritmos metaheurísticos de la literatura a los efectos de explorar su

performance. La experimentación es realizada en instancias reales de la ciudad de Bahía Blanca, Argentina, así como en conocidos *benchmarks* de la literatura.

El presente artículo se encuentra estructurado de la siguiente forma. En la Sección 2 se presenta el problema abordado y una revisión bibliográfica de los principales trabajos relacionados, en la Sección 3 se proponen los algoritmos de resolución utilizados, en la Sección 4 se desarrolla la experimentación computacional y, finalmente, en la Sección 5 se presentan las principales conclusiones de este trabajo.

2 Problema abordado

La gestión de los residuos sólidos urbanos en la ciudad de Bahía Blanca es una actividad crucial para las autoridades locales, no sólo por el amplio impacto ambiental y social asociado a su operatoria sino también porque consume una gran parte de los recursos presupuestarios del municipio [33]. Por lo tanto, enfoques que permitan optimizar la logística de recolección pueden ser relevantes para lograr una prestación más eficiente del servicio [17]. En este marco es que se han realizado propuestas para migrar desde el actual sistema de recolección puerta a puerta a un sistema contenedorizado [17,33]. Continuando con estos estudios, en la siguiente sección se presenta un modelo matemático para planificar la siguiente etapa en la cadena logística inversa de los residuos sólidos urbanos: el diseño de las rutas de recolección de los residuos acumulados en los contenedores. Asimismo, se realiza una revisión de los principales trabajos relacionados de la literatura.

2.1 Modelo matemático

El problema de recolectar lo acumulado en los contenedores de residuos se puede asemejar a un problema de enrutamiento de vehículos con restricción de capacidad (CVRP, por sus siglas en inglés, *Capacitated Vehicle Routing Problem*). El mismo puede modelarse matemáticamente de la siguiente forma. Dado un conjunto de contenedores C y un superconjunto $\underline{C} = C \cup c_0$, donde c_0 es el depósito donde inician y finalizan su recorrido los vehículos, se definen las siguientes variables y parámetros. La variable binaria x_{ij} que adopta el valor 1 si un vehículo utiliza el camino desde el contenedor $i \in C$ al contenedor $j \in C$, 0 en caso contrario y la variable continua positiva u_i que indica la carga del vehículo antes de llegar al contenedor $i \in C$. Luego se definen los parámetros Q como la capacidad del vehículo, d_{ij} como la distancia entre los contenedores $i \in I$ y el contenedor $j \in I$ y q_i como la cantidad de residuo a recolectar en el contenedor $i \in I$. De esta forma, se plantea el siguiente modelo, utilizando la formulación de dos-índices propuesta por [3] en las Ecuaciones (1)-(6).

$$\text{Minimizar } FO = \sum_{i,j \in \underline{C}} x_{ij} d_{ij} \tag{1}$$

Sujeto a:

$$\sum_{j \in \underline{C}} x_{ij} = 1, \ \forall \ i \in C \tag{2}$$

$$\sum_{j \in \underline{C}} x_{ji} = 1, \ \forall \ i \in C, \tag{3}$$

$$u_j - u_i \leq Q\left(1 - x_{ij}\right) - q_j, \ \forall \ i,j \in \underline{C} \tag{4}$$

$$q_i \leq u_i \leq Q, \ \forall \ i \in C \tag{5}$$

$$x_{ij} \in \{0,1\}, \ \forall \ i,j \in \underline{C} \tag{6}$$

El objetivo planteado consiste en minimizar la distancia total recorrida expresada en la Ecuación (1). Las Ecuaciones (2) y (3) garantizan que cada contenedor sea visitado una única vez, teniendo un único contenedor sucesor y un único contenedor predecesor en la ruta. La Ecuación (4) impide la formación de *subtours*. La Ecuación (5) garantiza que la capacidad del vehículo no sea sobrepasada. La Ecuación (6) establece la naturaleza binaria de la variable x_{ij}.

2.2 Revisión bibliográfica

El problema de recolección de residuos contenedorizados en una ciudad ha sido abordado frecuentemente en la literatura En [4] y [5] se desarrollan extensas revisiones sobre estos trabajos.
En el caso de Argentina pueden encontrarse algunos trabajos sobre aplicaciones de modelos VRP para resolver el problema de diseño de rutas de recolección. Por ejemplo, en [6] y [7] se implementan modelos de programación matemática para planificar las rutas de recolección de contenedores de residuos en la zona sur de la Ciudad de Buenos Aires. Por otro lado, en [8] se trabaja optimizando las rutas en esta zona teniendo como objetivos minimizar las distancias de recorrido simultáneamente con la minimización del desgaste de los vehículos. En la ciudad de Concordia, [9] presenta una aplicación para diseñar las rutas de recolección de la ciudad haciendo un esfuerzo por minimizar la cantidad de giros para facilitar la implementación de las rutas por las autoridades. Por otra parte, [10] exhibe un algoritmo para resolver la zonificación de la ciudad de San Miguel de Tucumán a los efectos de optimizar el uso de recursos, reasignando camiones hacia la zona céntrica de la ciudad. En [11] y [12] mediante modelos de programación entera se planifica la recolección de residuos reciclables en la ciudad de Morón. En [13] se presenta un enfoque integral que determina la localización de los contenedores, así como el diseño de la ruta que efectúa la recolección de su contenido en instancias simuladas de Bahía Blanca. En la misma ciudad, [14] y [15] exponen modelos de ruteo de vehículos con balanceo de distancias entre las distintas rutas para diseñar los recorridos de los recolectores informales de residuos reciclables.

3 Método de resolución propuesto

Como se mencionó anteriormente, la recolección de RSU en contenedores constituye un caso de aplicación del problema VRP (*Vehicle Routing Problem*). En teoría de complejidad computacional, este tipo de problemas están clasificados como NP-hard [16], es decir, es a lo sumo tan difícil como los problemas para los cuales no se han desarrollado aún algoritmos de resolución eficientes que se ejecutan en tiempo polinomial con respecto al tamaño del problema [17]. En este tipo de problemas las herramientas metaheurísticas permiten obtener buenas soluciones en tiempos de cómputo razonables. El algoritmo de resolución que se propone se basa en una estrategia de recocido simulado (SA, *Simulated Annealing* en inglés) y fue adaptada de los trabajos [18] y [19]. SA es un método basado en la búsqueda local que se desarrolló a partir de una analogía con el fenómeno físico de recocido [20] para resolver problemas complejos de optimización. Los métodos de búsqueda local buscan la solución con un mejor valor del criterio elegido en el entorno de la solución actual, la aceptan como la solución actual y repiten este procedimiento hasta que no resulte posible mejorar la solución en el entorno explorado. Mediante la aplicación sistemática de este procedimiento se obtiene, en general, un óptimo local para el problema. Para evitar quedar atrapado en un óptimo local, se debe incorporar un mecanismo de diversificación con el fin de explorar adecuadamente el espacio de soluciones. En la metaheurística de recocido simulado, la estrategia de diversificación permite movimientos, con cierta probabilidad, hacia soluciones que empeoran el valor actual de la función objetivo.

Para obtener una buena aproximación a la solución óptima del problema durante el proceso de búsqueda, resulta necesario reiniciar la búsqueda regularmente desde una de las soluciones aceptadas durante el proceso de búsqueda seleccionada al azar. El algoritmo SA incorpora los parámetros clásicos del recocido simulado. Seguidamente se indican los parámetros y variables correspondientes al algoritmo SA implementado.

- t : iteración actual.
- S_0 : solución inicial.
- S_A : solución actual.
- S_c : solución candidata.
- $V(S)$: entorno de la solución S, dado por el conjunto de soluciones que pueden obtenerse a partir de S mediante un movimiento o perturbación elemental.
- T : parámetro de control (que simula la temperatura en el proceso físico del recocido). Es un valor positivo que varía desde un valor inicial mayor, T_0, a otro que es menor, T_f, durante la ejecución del algoritmo.
- N_T : número de iteraciones realizadas por el algoritmo para cierto valor de T.
- $\alpha(T)$: función que determina el mecanismo de enfriamiento, es decir, la evolución de T durante la ejecución del algoritmo. En general, $\alpha(T) = \alpha T$, en la práctica $\alpha \in [0,8; 0,99]$.
- N_{cont} : número de iteraciones sin mejora en la iteración t.

- N_{stop} : número máximo de iteraciones permitidas sin mejora.

Se aplica el siguiente pseudo-código para determinar una solución potencialmente óptima.

Algoritmo de Recocido Simulado

i. Inicialización

Se utiliza un procedimiento constructivo aleatorizado para generar una solución inicial, S_0.
Se evalúa la función objetivo, $FO(S_0)$, empleando la Ecuación (1).
S_0 se adopta como solución actual S_A, $N_{cont} = t = 0$, $T = T_0$.

ii. Iteración t

Se genera aleatoriamente una solución candidata en el entorno de S_A, S_c $V(S_A)$.
Se evalúa $FO(S_c)$.
Se calcula $FO = FO(S_c) - FO(S_A)$.
Si $FO \leq 0$, $S_A = S_c$, $N_{cont} = 0$. *Obs: la nueva solución es aceptada.*
En otro caso, $p_A = e^{-\frac{FO}{T}}$. *Obs: la nueva solución es aceptada con probabilidad* p_A.
Se genera un número aleatorio uniformemente distribuido en el intervalo [0;1]:
Si $\leq p_A$, $S_A = S_c$, $N_{cont} = 0$;
En otro caso, $N_{cont} = N_{cont} + 1$.

$$t = t + 1$$

Si t es un múltiplo de N_T, entonces $T = \alpha(T)$
Si $N_{cont} = N_{stop}$ o $T \leq T_f$, se detiene la ejecución.

3.1 Metaheurísticas de comparación

Las metaheurísticas de comparación son el algoritmo de *Large Neighborhood Search* (LNS) desarrollada por Erdoğan [21] y un algoritmo genético estándar.

La metaheurística de Erdoğan fue adaptada a partir de la heurística conocida como *adaptative* LNS desarrollada por Pisinger y Ropke [22] que extiende la heurística original de Shaw [23]. Una explicación simplificada de su funcionamiento y pseudo-código (ver Fig. 1) puede consultarse en [24].

El funcionamiento de la heurística está constituido por dos etapas principales. La primera, es la construcción de una solución inicial que se obtiene insertando clientes en las rutas disponibles de acuerdo con el objetivo a minimizar (operador Sol-Inicial). Luego, se realiza una mejora mediante el operador *Local-Search* que aplica cuatro técnicas de búsqueda local. Las primeras tres son conocidas como Exchange (se intercambian dos clientes), 1-OPT (se extrae un cliente de una ruta y reinserta en otra) y 2-OPT (se intercambian dos segmentos de rutas). Estos operadores se encuentran detallados en [25]. El cuarto operador de búsqueda local es *Vehicle-Exchange*. Este operador intenta intercambiar los vehículos asignados a dos rutas, por lo cual es útil cuando se trabaja con flota heterogénea.

La segunda etapa es donde se intenta obtener un mejoramiento de la solución de la etapa anterior. Se aplica, el operador *Destroy-And-Rebuild* que altera de manera considerable la solución actual para explorar otra región del espacio de búsqueda y así poder escapar de óptimos locales. Particularmente, se extraen tramos extensos de

rutas de la solución actual y los clientes extraídos vuelven a reinsertarse en aquellas posiciones que minimicen la función objetivo (*Cost*). Una solución es aceptada si tiene un mejor costo que la mejor solución hallada hasta el momento o, en caso de que una solución no tenga mejor costo que la solución anterior, puede incluso ser aceptada con una probabilidad *p-value*. Este proceso se repite cíclicamente hasta el límite temporal impuesto por el usuario.

```
1: procedure LNS(input)          ▷ Como input se ingresa la información
   correspondiente a los clientes, vehículos y lugares de descarga (depots)
2:     S ← SolInicial()
3:     S' ← LocalSearch(S)
4:     BestS ← S'
5:     repeat
6:         S' ← DestroyAndRebuild(S')
7:         S' ← LocalSearch(S')
8:         if (Cost(S') <= Cost(S')) then
9:             BestS ← S'
10:        else
11:            p ← Random(0, 1)
12:            if (p <= pvalue) then
13:                S' ← BestS
14:            end if
15:        end if
16:    until Time elapsed > Time limit
17:    return BestS
18: end procedure
```

Fig. 1. Algoritmo LNS implementado en [21]. Fuente de la imagen: [24].

El algoritmo genético genérico fue desarrollado utilizando el *framework Distributed Evolutionary Algorithms in Python* (DEAP) [26]. Este posee las siguientes características:

Representación de las soluciones. Las soluciones se codifican como una permutación de enteros de longitud igual al número de contenedores *n*. Cada índice en el vector representa el orden de visita en el recorrido y el valor entero correspondiente representa uno de los contenedores.

Inicialización. La población de tamaño #*P* se inicializa aplicando un procedimiento aleatorio para generar las permutaciones con una distribución uniforme.

Operadores genéticos. El operador de recombinación es el *Crossover* parcialmente mapeado (PMX) aplicado sobre dos individuos seleccionados con probabilidad p_c. El operador de mutación se basa en *Swap Mutation* e intercambia dos elementos de la permutación. La mutación se aplica a un individuo con probabilidad p_m. Los operadores propuestos garantizan la factibilidad de la solución.

Selección, La selección es realizada a través de un torneo binario, de los cuales se selecciona el de mejor fitness.

Reemplazo. En cada iteración la población nueva está conformada por el mejor 10 % (con mejor *fitness*) de la población anterior y el resto por individuos nuevos generados a través de los operadores genéticos.

Evaluación de *fitness*. La función de *fitness* es decodificada leyendo los alelos de izquierda a derecha e insertando una visita al depósito cuando es necesario.
Análisis paramétrico. Los parámetros que fueron analizados mediante un análisis estadístico fueron el tamaño de la población $\#P$ -se consideraron los valores 100; 150 y 200- la probabilidad de mutación p_m -se consideraron los valores 0,05; 0,1; 0,15; 0,20 y 0,25- y de cruzamiento p_c -se consideraron los valores 0,5; 0,6; 0,7; 0,8; 0,9 y 1-. Los análisis paramétricos se realizaron sobre las instancias P-n16-k8, P-n19-k2 y P-n20-k2 propuestas en [27]. Para cada instancia y para cada configuración paramétrica se realizaron 50 ejecuciones independientes. Se aplicó la prueba de Shapiro-Wilk para estudiar si la distribución de fitness tenía una distribución normal. Debido a que numerosas ejecuciones no se ajustaron a una distribución normal se evaluaron las medianas a través de la prueba de Friedman, seleccionándose la siguiente configuración: $\#P = 200$, $p_c = 0{,}9$ y $p_m = 0{,}25$.
Corte por estancamiento. Se incorporó un mecanismo de corte por estancamiento. El algoritmo se detiene cuando no se obtiene ninguna mejora en el fitness del mejor individuo durante un intervalo de tiempo igual al 50% del tiempo máximo de ejecución (Eq. (7)) de la instancia. En caso contrario, continúa hasta efectuar la generación –ciclo evaluación, selección, cruzamiento, mutación y reemplazo- que al finalizar haya sobrepasado el tiempo máximo de ejecución.

4 Resultados

Los resultados obtenidos corresponden a la resolución de cuatro escenarios reales de la logística de recolección de RSU de Bahía Blanca construidos en los trabajos [28] y [29]. Asimismo, la experimentación correspondiente a los enfoques metaheurísticos fue ampliada con la resolución problemas de un *benchmark* de la literatura.

4.1 Pruebas realizadas sobre escenarios reales

Los escenarios planteados en [28] y [29] constituyen casos reales diseñados en función del problema de RSU existente en la ciudad de Bahía Blanca.

Se estudian dos planificaciones distintas para la disposición de los contenedores, considerando la recolección de ambas fracciones de residuos: tanto los secos como los húmedos. Dichas planificaciones contemplan dicha opción de separar los contenedores en residuos húmedos y secos a la vez que consideran la opción de utilizar diferentes frecuencias de recolección. Las planificaciones difieren fundamentalmente en cuanto a la frecuencia con la cual se plantea recolectar los residuos secos, conformándose de esta manera los siguientes cuatro escenarios:

Escenario 1:
- Frecuencia de recolección [veces/semana]: 6.
- Tipo de residuo a recolectar: húmedo.

Escenario 2:
- Frecuencia de recolección [veces/semana]: 4.
- Tipo de residuo a recolectar: seco.

Escenario 3:

- Frecuencia de recolección [veces/semana]: 6.
- Tipo de residuo a recolectar: húmedo.

Escenario 4:

- Frecuencia de recolección [veces/semana]: 3.
- Tipo de residuo a recolectar: seco.

Resulta necesario aclarar que las diferencias indicadas entre los distintos escenarios repercuten esencialmente en la cantidad de contenedores que se utilizarán, sin embargo, la explicación de este hecho no forma parte de los objetivos planteados para este trabajo.

Para la resolución exacta se implementó mediante el software CPLEX versión 12.6.0.0 en un entorno de GAMS, utilizando la versión de paralelismo oportunista de dicho software, con la adición de la inecuación válida del mínimo número de viajes para acelerar la convergencia. Se fijó un límite de tiempo para cada ejecución de 15 000 segundos.

Tanto el algoritmo de *SA* como el de LNS fueron programados mediante la interfaz de *Visual Basic for Applications* (VBA) de MS Excel. Mientras que, para llevar a cabo el algoritmo de GA, fue utilizada la librería DEAP y se empleó Python como lenguaje de programación.

Cada algoritmo se ejecutó en distintos computadores personales, realizando 50 corridas para cada instancia con el fin de obtener una muestra más representativa del rendimiento de los algoritmos.

Los resultados obtenidos se exponen a continuación en las Tablas 1 y 2. En la primera se puede observar la mejor distancia -FO según Ec. (1)- obtenida para cada escenario de RSU con cada uno de los métodos propuestos de resolución. Para la solución de CPLEX, se reporta el *gap* calculado por el software, el cual indica que no se halló el valor óptimo en los escenarios 2 y 4. En la segunda tabla se contrastan tres indicadores de los conjuntos de soluciones obtenidos para cada metaheurística, una medida de centralización, como lo es el valor promedio de los resultados obtenidos, una medida de dispersión, esto es, el desvío estándar, y el *gap* promedio. El *gap* es calculado como la diferencia entre el valor promedio y el valor obtenido por CPLEX, dividida por este último.

Tabla 1. Resultados del problema de RSU: mejores soluciones de cada metaheurística.

Instancia	Resolución exacta CPLEX		Mejor resultado FO metaheurísticas		
	FO	CPLEX gap %	SA	LNS	GA
Escenario 1	22613,90	0,00	22814,00	22877,00	36712,00
Escenario 2	41533,28*	26,35	43763,00	43491,00	48561,00
Escenario 3	27150,00	0,00	27707,00	27648,00	49463,00
Escenario 4	62800,63*	18,33	65995,00	65938,00	71185,00

* Debido a que no se encontró la solución óptima para estos escenarios, los valores corresponden al mejor valor hallado por CPLEX para el tiempo de ejecución (*Upper Bound*).

Tabla 2. Resultados del problema de RSU: performance media de cada metaheurística.

Escenario	SA			LNS			GA		
	FO promedio	Desvío est.	gap %	FO promedio	Desvío est.	gap%	FO promedio	Desvío est.	gap%
Escenario 1	23310,12	216,82	3,08	23542,56	246,68	4,11	39041,70	1164,59	72,65
Escenario 2	44294,64	291,85	6,65	44229,92	303,77	6,49	51047,52	1247,72	22,91
Escenario 3	28143,00	296,63	3,66	28032,34	223,30	3,25	53408,00	1396,83	96,99
Escenario 4	66366,31	202,49	5,68	66356,19	180,61	5,66	73290,82	1096,94	16,70

El tiempo de ejecución máximo de todas las metehaurísticas se estableció proporcionalmente a la cantidad de nodos de la instancia -excluyendo al depósito- y deviene de la Ecuación (7).

$$Tiempo\ Máximo\ de\ Ejecución\ [seg] = \frac{(n°\ de\ nodos * 15 * 60)}{50} \quad (7)$$

Debe tenerse en cuenta que tanto el SA como el GA aquí descriptos cuentan con mecanismos de corte por estancamiento que pueden llevar a un tiempo real de ejecución sea inferior al máximo. Esto no es así para el LNS cuyo tiempo de ejecución será igual al máximo.

Si bien al momento de ejecutar los escenarios RSU en CPLEX se limitó el tiempo en 15 000 segundos, en los escenarios 1 y 3, en los que se alcanzó el valor óptimo, se hizo un corte de forma más temprana, habiendo consumido 1892 segundos en el primer escenario y 4367 segundos en el escenario 3.

A modo de evaluar su desempeño, en la Tabla 3 se registra la cantidad de iteraciones que requirió cada metaheurística en el tiempo establecido por la ecuación previamente mencionada.

Tabla 3. Tiempo e iteraciones promedio requeridos para los escenarios de RSU.

Escenario	Tiempo de cómputo máximo (en segundos)	Número promedio de iteraciones realizadas		
		SA	LNS	GA
Escenario 1	1242	76860,12	33700,22	30739,22
Escenario 2	1242	211455,16	16724,16	50439,62
Escenario 3	1422	265653,78	11563,00	51479,40
Escenario 4	1422	1516847,40	6129,72	63967,20

4.2 Pruebas realizadas sobre *benchmark* de la literatura

Para la ampliación de la comparación de metaheurísticas se utilizaron algunas instancias del conjunto de *benchmark* propuesto en [30], denominado Conjunto E. Tanto las instancias como las soluciones óptimas fueron descargadas del repositorio digital VRP-REP [32].
A continuación, se observa en la Tabla 4 los mejores resultados hallados en cada instancia por los algoritmos en estudio, mientras que en la Tabla 5 se ve reflejado el rendimiento de las metaheurísticas mediante los mismos parámetros utilizados para evaluar el desempeño en RSU.

Tabla 4. Resultados del conjunto E: mejores soluciones conocidas de cada metaheurística.

Instancia	Solución óptima	Mejor resultado FO metaheurísticas		
		SA	LNS	GA
E-n13-k4	247,00	247,00	247,00	247,00
E-n22-k4	375,00	375,00	375,00	375,00
E-n23-k3	569,00	569,00	619,00	569,00
E-n30-k3	534,00	503,00*	534,00	529,00*
E-n31-k7	379,00	379,00	379,00	427,00
E-n33-k4	835,00	835,00	835,00	859,00
E-n51-k5	521,00	521,00	521,00	582,00

* Las soluciones encontradas tienen un menor valor de FO, pero mayor cantidad de rutas (k = 4) que la solución de referencia, hecho que se observa también en la Tabla 5.

Tabla 5. Resultados del conjunto E: Performance media de cada metaheurística.

Instancia	SA			LNS			GA		
	FO	Desvío est.	*gap* %	FO	Desvío est.	*gap* %*	FO	Desvío est.	*gap* %
E-n13-k4	247,08	0,27	0,03	247,00	0,00	0,00	247,72	1,09	0,29
E-n22-k4	376,14	3,24	0,30	375,00	0,00	0,00	393,94	14,90	5,05
E-n23-k3	569,04	0,20	0,01	619,00	0,00	8,79	625,086	41,06	9,85
E-n30-k3	503,04	0,28	-5,80	535,08	1,45	0,20	583,86	36,37	9,34

E-n31-k7	394,34	13,11	4,05	379,64	2,16	0,17	485,44	31,18	28,08
E-n33-k4	836,44	2,21	0,17	835,00	0,00	0,00	903,42	23,11	8,19
E-n51-k5	522,48	3,81	0,28	521,84	2,76	0,16	645,56	29,05	23,91

* El *gap* fue calculado como la diferencia entre el valor promedio y el óptimo, dividida por este último.

Al igual que la Tabla 3, se registraron el promedio de iteraciones alcanzadas en cada metaheurística en el tiempo dado por la Ecuación (7).

Tabla 6. Tiempo e iteraciones promedio realizadas por instancia.

Instancia	Tiempo de cómputo máximo (en segundos)	Número promedio de iteraciones realizadas		
		SA	LNS	GA
E-n13-k4	216	76860,12	33700,22	30739,22

E-n33-k4	576	3614994,88	4502,92	68233,54
E-n51-k5	900	6460189,50	2788,66	91230,70

4.3 Análisis de resultados

A partir del análisis de los resultados se verifica que los tres procedimientos metaheurísticos resultan válidos para utilizarlos en la resolución de los problemas del tipo CVRP.

Es necesario aclarar que tanto SA como GA encuentran un valor menor al óptimo reportado en la bibliografía para la instancia E-n30-k3 dado que, al no contar con una restricción que indique el número de rutas, presentan una solución con una ruta adicional. Es por este motivo también que se ve observa un valor negativo del gap en dicha instancia dentro de la Tabla 5 para el SA.

La experiencia realizada sobre *benchmark* y posteriormente sobre los escenarios de RSU, marcó un buen rendimiento tanto del algoritmo propuesto SA como el LNS de la literatura al arrojar valores considerablemente pequeños del *gap* promedio. Por otra parte, GA mostró en comparación con el SA y el LNS un bajo rendimiento que se ve reflejado nuevamente en el *gap* promedio, posiblemente se deba a que se utilizó un algoritmo genético estándar con una función de decodificación simple tomada de aplicaciones en problemas irrestrictos como el Problema Agente Viajero.

En cuanto a las iteraciones promedio realizadas, se observa que SA y GA alcanzan mayor cantidad de iteraciones a medida que crece la cantidad de nodos, no sucede lo mismo en el caso de LNS para el que donde el número de iteraciones disminuye al aumentar la cantidad de nodos.

5 Conclusiones

Encontrar nuevas herramientas para volver más eficiente la logística de residuos sólidos urbanos (RSU) constituye una inquietud acuciante en las sociedades actuales. Este trabajo está centrado en la resolución de problemas de recolección de residuos para el área de Bahía Blanca. Particularmente se aborda una problemática encontrada en trabajos previos donde la resolución exacta de problemas de recolección de residuos resultaba ineficiente, debido a que se requería la partición de los escenarios en porciones más pequeñas para lograr la convergencia a una solución factible aceptable.

Por ello, en este trabajo se presenta un estudio comparativo entre la resolución exacta y tres herramientas metaheurísticas de resolución para el problema de la recolección de RSU en Bahía Blanca. La resolución exacta está basada en una formulación de programación matemática del modelo CVRP mediante el software CPLEX. Por otro lado, en lo que concierne a la resolución metaheurística se propone un algoritmo de recocido simulado que es comparado contra un algoritmo tomado de la literatura basado en *Large Neighborhood Search* (LNS) y un algoritmo genético estándar. Además, se extiende la comparación de las metaheurísticas con algunas instancias de un conocido *benchmark* de la literatura. El algoritmo de recocido simulado propuesto tiene un desempeño similar que el algoritmo LNS de la literatura -obteniendo en varias ocasiones valores cercanos a la solución óptima- y supera marcadamente al algoritmo genético estándar.

Luego del trabajo experimental realizado, se puede afirmar que la aplicación de estos algoritmos redunda en la obtención de resultados potencialmente aceptables y competentes, contando las metaheurísticas con la ventaja del menor esfuerzo de cómputo requerido para llegar a la solución.

Como líneas de trabajo a futuro se tiene previsto experimentar con escenarios de mayor tamaño de la ciudad Bahía Blanca, utilizando las metaheurísticas propuestas, que fueron validadas en el presente trabajo. Por otro lado, se propone continuar mejorando la formulación de programación matemática, implementada a través de CPLEX, mediante la inclusión de inecuaciones válidas adicionales que permitan reducir los tiempos de resolución. Además, se propone desarrollar la función de codificación del algoritmo genético con un enfoque que se adapte mejor al tipo de problema CVRP abordado.

Agradecimientos

Los autores de este trabajo desean agradecer el financiamiento recibido de la Universidad Nacional del Sur para el desarrollo de los proyectos PGI 24/J084 y PGI 24/ZJ35. Además, el primer autor de este trabajo agradece el financiamiento recibido

del Consejo Interuniversitario Nacional (CIN) a través de una Beca de Estímulo a las Vocaciones Científicas.

Abstract. This work presents a comparison framework to evaluate different optimization heuristics applied to discrete event simulation. The proposal incorporates variance reduction techniques and dynamic runs with the purpose of improving the heuristics' results and computational costs. The framework was tested on optimization problems based on two different discrete event simulation models and three different metaheuristics: simulated annealing, genetic algorithms, and tabu search. The implementation of the framework yields positive results in the search of the global optimums, especially for stochastic noise sensible algorithms such as simulated annealing.

Keywords: Simulation-based optimization · Comparative analysis · Variance reduction

1 Introduction

The use of optimization methods is a powerful tool to support decision making in any industry. At the same time, simulation techniques can be used to replicate real systems and evaluate different scenarios given the uncertainty and complexity faced by the decision-maker, without conducting expensive experiments.

The combination of simulation-based methods and optimization have been extensively used in the last decades for finding the best configurations and responses of complex systems. Despite the constant improvements of computational hardware, the lack of computational resources is still an issue for the implementation of these methods. Therefore, the utilization of techniques and algorithms that deal appropriately with the variability of the responses of real systems is a common subject of investigation for many researchers.

One of the main characteristics of simulation optimization is the black-box approach that must be used to search for local optimums. Since in most of the simulation models

a mathematical expression of the system is not available, strategies that evaluate only the input and responses of the model are necessary for the exploration of the search space of possible configurations for the system.

On the other side, the variability of the response of the model is an element that must be considered in the implementation of these techniques. Because of the stochastic nature of real systems, simulation-based methods replicate the variance of the processes that are being modeled. The latter gives simulation optimization another aspect that must be addressed: the costs of estimating the actual response of a specific configuration of the system. Because of the variability of the response, an estimation of the output is necessary to evaluate the objective function of the optimization problem. To improve the statistical significance of the estimation, additional runs of the model are needed to obtain an accurate value of the function, adding computational costs in the execution of the optimization method.

These two elements represent the main challenges of simulation-optimization techniques. While the black-box approach limits the available methods for solving the optimization, the stochastic nature of simulation adds additional computational costs for the evaluation of the objective function. These characteristics and the fact that the optimization problems usually have a large search space makes the heuristic methods that explore only a fraction of the search space a common choice for achieving positive results.

Also, these aspects justify the use of statistical techniques applied to the model to reduce the estimation error that may mislead the heuristic's exploration of the search space [10] while improving the operation and results of the optimization algorithms with limited computational costs. The presented work explores different techniques and optimization algorithms that contribute to this purpose.

The remainder of this paper is organized as follows. In Section 2 a literature review is conducted considering recent simulation optimization studies and similar proposals. Section 3 presents the optimization heuristics and statistical techniques used in the study. Section 4 describes the proposed framework that incorporated the described techniques and different post-optimization analysis. Section 5 shows the preliminary testing based on the execution of two test simulation models for each of the selected heuristics. Finally, section 6 presents the conclusions of the work and suggests future research lines.

2 Literature Review

The specialized literature presents many study cases of applications of simulation-based optimization using heuristics. Rezaeiahari and Khasawneh [18] propose a simulation-optimization approach to solve the scheduling problem of medical tourists who travel to destination medical centers (DMCs). In their work, the authors compare the performance of the two metaheuristics optimization procedures: simulated annealing and tabu search. Their approach considers a simulation evaluation at each iteration of the optimization process. The objective of the work is to determine the best schedules for the medical tourist considering their preferred hours and minimizing the total attention

times of the exams. Their results show low differences in the utilization of tabu search or simulated annealing.

Lu et al [14] propose a genetic algorithm-based simulation-optimization method to solve the integrated inventory management process that considers five different policies: schedule-based, cost-based, demand-based, schedule-cost-based, and schedule-demand-based policies. Their work aims to determine how much material to stock and different strategies for the prioritization of materials in the construction project to avoid delays. The authors test the proposed methodology in a set of fictitious project networks.

Another contribution to the literature is presented by Haddock and Mittenthal [7]. They propose a simulated annealing algorithm with a simulation model to determine the optimal parameter levels at which to operate a system. They present numerical testing of a hypothetical simulation model and provide recommendations for a proper parameter tuning of the algorithm.

Rabe et al. [16] also explore simulation-optimization implementations using dynamic runs and solution filters in discrete-event simulation while executing a genetic algorithm to solve a manufacturing case study. This work also has relevance to this study because of its focus on approaching the computational cost problem related to simulation-optimization methods.

We can also find contributions to the literature that explore variance reduction techniques. Abourik et al [1] explore the uses of the common random numbers technique with a simulation model, obtaining positive results on the variance reduction of the difference between configurations. Mawlana and Hammad [15] implemented the same technique to execute a preliminary study that determined the number of replications that a simulation model should execute in conjunction with a genetic algorithm. The authors [1,15] report savings of 58.8% and 80.97% in the simulation runs needed for achieving a certain variance level. Finally, the publication that shares the most common objectives with this work is the proposal of Anderson et al. [2], which explores the usage of the scatter search heuristic using common random numbers, antithetic variates, and dynamic runs in conjunction to improve the results of the optimization heuristic.

While Abourik et al [1], and Mawlana and Hammad [15] use the variance reduction techniques to conduct a preliminary study of the replications needed, Anderson et al. [2] implement these methods to dynamically save simulation runs in the execution of the algorithm. Nevertheless, none of these works explore the interactions of these techniques in a simulation-optimization context.

3 Heuristics and techniques

3.1 Optimization Heuristics

According to the objectives of this study, three metaheuristics that have been extensively used in the literature are considered in this work: simulated annealing, genetic algorithms, and tabu search, that are further described.

Simulated Annealing

Proposed by Kirkpatrick, et al [11], simulated annealing (SA) operates by emulating the thermodynamic process in which a system tries to find an equilibrium point that minimizes the total energy [4]. The algorithm operates evaluating a candidate configuration x_i' for the objective function $f(x)$ randomly selected from the neighborhood of the initial configuration x_i for each iteration i. The configuration x_i' is accepted as the initial configuration of the next iteration by the probability shown in Equation 1.

$$Pr\ (Acceptance) = \begin{cases} 1, & f(x_i) < f(x_i') \\ e^{\frac{f(x_i') - f(x_i)}{t}}, & \sim \end{cases} \quad (1)$$

Equation 1 shows that a better configuration is always selected while a worse configuration may be selected depending on the value of t, which represents the temperature of the iteration. The temperature t is determined by the temperature schedule which is the main parameter of the algorithm. This schedule is defined by the initial temperature, the final temperature, and how the temperature decreases in each iteration. There are different alternatives to define the cooling schedule. For instance, the geometric, reciprocal, and logarithmic schedules are common options [4]. Also, the algorithm includes a parameter n_{max} that defines the number of iterations before a temperature decrease is applied.

The chance of selecting a worse configuration is incorporated in the algorithm to escape local optimums in the exploration of the search space. As the search proceeds, the value of t decreases to the point that it is impossible to accept a worse configuration, or the termination criteria is met.

Genetic Algorithms

A genetic algorithm (GA) is an evolutionary strategy that uses population-based iterations to recombine and select the best configurations available. With the assumption that the configurations of the objective function can be expressed in bit strings [24], the metaheuristic works with two main operators: crossover and mutation. In analogy to the biological concepts in which the algorithm is based, the crossover operator recombines the population of individuals that represent a set of configurations for the objective function. This recombination is based on a fitness value that is obtained by the value in the objective function of each individual.

Once obtained the fitness values of the population, an intermediate population of the same size as the initial population is randomly created selecting individuals with replacement according to a selection function. There are two main ways to define the fitness values and select the individuals for the intermediate population: proportional fitness assignment and rank-based fitness assignment [22].

Then, the crossover operator is applied to the intermediate population, recombining random pairs of individuals with a probability given by a crossover parameter. If a pair

of individuals are selected to recombine, then they exchange portions of their binary strings selected by a random position.

The final step of the iteration is the mutation operator, which changes the value of one position of the binary string of the individuals randomly and according to a probability given by the mutation parameter.

Tabu Search

Tabu search (TS) is a metaheuristic procedure designed for escaping local optima, proposed by Glover [5]. The algorithm considers the evaluation of possible movements by changing one bit of the binary representation of the initial configuration. After the evaluation of each neighborhood, the algorithm chooses the best movement for the next iteration, even if it means a worse value for the objective function. For escaping local optima, the algorithm limits the possible movement with a tabu list of size given by the parameter tuning. The tabu list restricts the available movements, forcing to select the next best possible movement of the neighbors and can be ignored if an aspiration criterion is met. In this work, we consider as an aspiration criterion to allow a tabu active move only if the resulting solution is better than the best one found, as it is typically implemented in the literature [22].

3.2 Statistical Techniques

The three metaheuristics described in the previous section require an evaluation of the objective function $f(x)$ to determine the direction of the exploration of the search space defined by the decision variables of the optimization problem. Using simulation-based methods to model complex systems, an estimation $f_n(x)$ must be used to evaluate the objective function $f(x)$, where n is the number of runs of the simulation model. The number of replications n increase the computational costs of running the simulation model and therefore the costs of solving the optimization problem. Nevertheless, a small number of runs will increase the estimation error of $f_n(x)$, deviating the search heuristics of the correct direction.

For example, at the last iterations of the simulated annealing, the chance of selecting a worse configuration for the next iteration is almost zero, but if the estimation error is too large, then the algorithm may wrongly conclude that the new configuration is better than the initial configuration. The latter may mislead the heuristic and affect the performance of the algorithm.

Because of this, variance reduction techniques (VRT) that may operate in a discrete-event simulation are considered in this work. These techniques take advantage of the operation of the random numbers that define the probability distribution of the processes of the model to reduce the variance of the results, decreasing the estimation error of $f_n(x)$ without incurring additional computational costs.

Also, a dynamic criterion for selecting the number of runs is applied to reduce even more the computational costs of the heuristic's operation.

Common random numbers

Common random numbers (CRN) is a variance reduction technique that can be applied in discrete-event simulations by inducing a positive correlation between the results of two different configurations of a simulation model. The underlying concept behind this technique is evaluating configurations under similar experimental circumstances in a way that the differences of responses of the configurations are caused by differences of the configurations rather than the variability of the systems [13]. This is possible using the same random number for the same processes in each configuration evaluated: if a process uses a low random number in one configuration then every compared configuration will use the same low random number in the same moment of the process.

The variability reduction is achieved in the variance of the differences between configurations. Using the same random numbers, the response of the system is positively correlated. Equation 2 shows how a positive correlation causes a variance reduction of the differences

$$Var\left[\frac{\sum_{j=1}^{n} Z_j}{n}\right] = \frac{Var[Z_j]}{n} = \frac{Var(X_{1j}) + Var(X_{2j}) - 2Cov(X_{1j}, X_{2j})}{n} \quad (2)$$

where X_{1j} and X_{2j} are responses of two different configurations for the j run, n is the total number of runs and $Z_j = X_{1j} - X_{2j}$. Given this equation, inducing positive correlations between X_{1j} and X_{2j} (considered in the covariate term in the equation) reduces the estimated variance of the difference of a certain metric in a simulation.

Antithetic variates

The antithetic variates (AV) technique operates in a similar way than common random numbers, with the difference that it induces a negative correlation between the replications of the same configuration. With this purpose, the technique synchronizes the random numbers of each pair of replications: if in the first run of the model a process uses a random number U in a given moment, for the next replication the model will use the random number $U - 1$ for the same process at the same moment. Equation 3 shows an unbiased estimator of the variance between the response of different runs

$$Var\left[\overline{X}(n)\right] = \frac{Var(X_j)}{n} = \frac{Var\left(X_j^{(1)}\right) + Var\left(X_j^{(2)}\right) + 2Cov(X_j^{(1)}, X_j^{(2)})}{4n} \quad (3)$$

where $X_j = \frac{(X_j^{(1)} + X_j^{(2)})}{2}$ (that is used to define an unbiased estimator of the variance between runs) and $X_j^{(1)}$, $X_j^{(2)}$ are responses of the model for one pair of replications of the configuration j. Equation 3 shows that inducing negative correlations between the replications of a certain configuration of the simulation model reduces the unbiased estimator of the variance of the results for each different configuration.

Dynamic Runs

This technique operates by defining a criterion for stopping the model given a certain variance in the results. Recommended by Hong and Nelson [8], the use of dynamic runs (DR) implies stopping the evaluation of additional runs when a variance threshold is reached. The latter causes a direct saving on the computational costs of the evaluation of the objective function. To define the threshold Anderson et al. [2] suggest that if the half-width of the confidence interval is 1% of the mean of the response's estimation, there's no need for more runs of the model. This criterion is expressed in Equation 4

$$0{,}01\,\bar{X} \;\geq\; t^{n-1}_{(1-\alpha)/2}\,\frac{s}{\sqrt{n}} \tag{4}$$

where $\bar{X}$ is the mean of the response for n replications.

4 Proposed Framework

Considering the metaheuristics and techniques, a framework is proposed for evaluating and improving the performance of simulation-optimization methods, saving computational costs, and enhancing the results of the optimization. This three-phase proposal is shown in Figure 1.

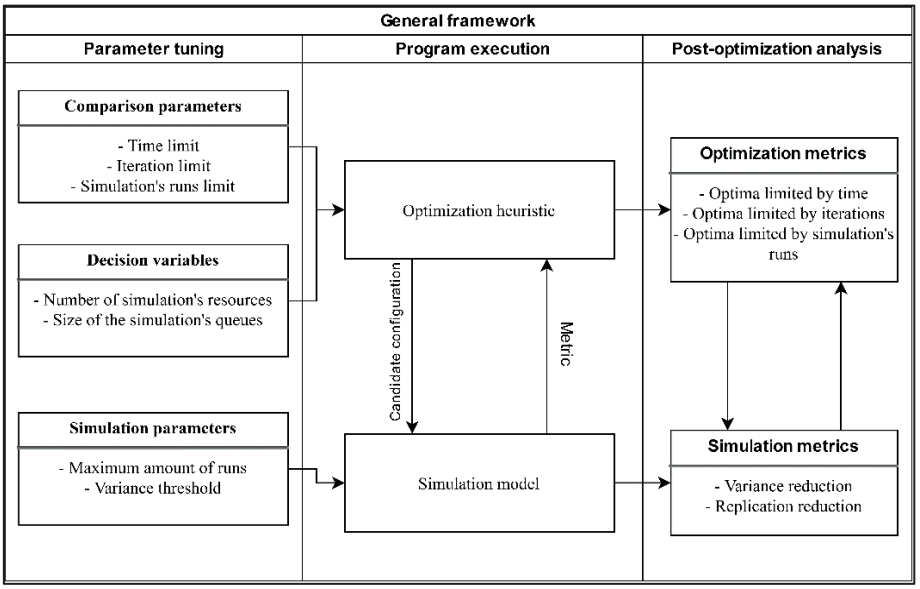

Fig. 1. Proposed framework

The first phase of the proposal is the parameter tuning needed for executing the corresponding simulation and heuristics which are divided into comparison parameters, decision variables, and simulation parameters. The comparison parameters define how to

limit the heuristics operation for adequate execution and subsequent evaluation. Three alternatives are proposed: limitations of time, iterations and simulation runs. The second set of parameters are the decision variables and the corresponding search space. These parameters are given by the optimization problem to solve. The third set of parameters to tune are the simulation-related parameters. These parameters are mainly the maximum amount of runs of the model for each evaluation and the variance threshold. While the former can be defined by sensitivity analysis, the latter can be selected by the suggestion made by Anderson et al. [2] explained in the previous section.

The following phase is the execution of the two systems that interact to solve the optimization problem: the selected heuristic and the simulation model.

Finally, the third phase of the proposal corresponds to a post-optimization analysis to determine the best combination of methods to solve optimization problems and the actual benefit of the techniques implemented. In this phase, two categories of metrics are evaluated: the ones related to the optima reached and the ones related to the simulation model. The first category evaluates the found optimums according to the limitations defined in the parameter tuning phase. The second category measures the variance reduced of the VRT implemented and the reduction of replications achieved by the dynamics runs criterion.

To evaluate the optimum-related metrics several tests and analyses are suggested. These are graphical analysis, parametric and non-parametric difference tests[1] , and a design of experiment (DOE) layout which evaluates the interactions of the methods and techniques implemented. For the simulation metrics, a measurement of the variance reduction for a sample and a quantification of the saved replications are proposed.

5 Numerical Experimentation: preliminary testing

In this section, we present the experimental design and results obtained by preliminary testing of the proposed framework presented in this manuscript. Section 5.1 describes the parameters tuning procedure, and section 5.2 describes the implementation of the simulation models. Section 5.3 presents numerical results.

5.1 Parameters Tuning

For the parameter tuning of the three metaheuristics proposed, a literature review was conducted to define an initial configuration of the parameters to perform preliminary experimentation and gain more insights from a comparative analysis among the three algorithms under the proposed framework. Even though better parameters for each metaheuristic exist, the focus of this work is not on the precise definition of the metaheuristic´s control parameters. To implement these metaheuristics three open-source R libraries were used: optimization for simulated annealing [9], tabuSearch for tabu search [3], and GA for genetic algorithms [20].

[1] Tests like the Student's paired *t*-test and Anova for the parametric case and the Wilcoxon signed-rank test and the Friedman test for the non-parametric scenario.

In terms of the simulated annealing algorithm, it is required that the temperature schedule defines a high temperature for the first iteration and a low temperature for the last iterations. For the temperature schedule, Stander and Silverman [21] report similar performances for logarithmic, exponential, and geometric schedules. For the preliminary testing of SA, a geometric schedule is considered, as indicated by Equation 5

$$\tau_i = f \left(\frac{l}{f}\right)^{\frac{(i-1)}{(T-1)}} \tag{5}$$

where τ_i is the temperature of the iteration i, T the size of the schedule (defined by the number of iterations of the algorithm), f the initial temperature, and l the final temperature. The values of the parameters considered for the experimentation were defined according to some references in the literature such as [7]. For the preliminary experimentation, it was decided to use a final temperature l of 5, a decrease rate of 0.8, and a number of iterations n_{max} of 8. Among these parameters, the most relevant for the implementation of the algorithm was the final temperature l that was chosen evaluating the magnitude of the objective function and the possible differences between configurations. Considering the smoother temperature decrease rate of a geometric schedule and the possible magnitudes of the differences between configurations, a value of 5 allows enhancing the intensification features of the algorithm. The rest of the parameters (f and T) are defined by the number of iterations for the algorithm. Also, to determine how the domain of the function is search, which means how are we going to select the candidate solutions at each iteration, a visiting function is defined based on a uniform distribution with a range given by a factor that depends on the historical ratio of invalid trials (out-bounded values) of solutions [9].

In the case of the genetic algorithms, three parameters must be tuned: the size n of the populations, the crossover and mutation rates. For the selection of the population size, Reeves [17] suggests the relation given by Equation 6

$$P = \left(1 - \left(\frac{1}{2}\right)^{M-1}\right)^{l} \tag{6}$$

where M is the size of the population, l the number of bits (given by the decision variables), and P the chance of every point in the search space being reached. The author suggests a value of at least 99% for P. For the given search space of the simulation models, the number of bits of the variables is 18, resulting in a population size of 12. This population size maximizes the performance of the algorithm while minimizing the computational costs (which increases with bigger populations). For the rest of the genetic algorithm parameters, Grefenstette [6] explores different values concluding that rates of 0.88 for the crossover and a value above 0.05 for the mutation rate are adequate for small-sized populations. Therefore, rates of 0.88 and 0.1 are chosen for these parameters. Finally, a linear ranking-based selection function was implemented with a selection pressure of 0.5 for the preliminary testing as it was the default value that allows to balance the diversification and intensification features of the algorithm.

Finally, for the tabu search, Fouskakis and Draper [4] suggest a tabu list's size of the square root of the number of bits that represent the decision variables. Considering that the amount of bits is 18, an approximation of 4 is made for this value. The last parameter

to decide is the number of neighbors evaluated in each iteration. To select the value of this parameter, a sensibility analysis was conducted executing the algorithm with 5 iterations starting from the same random configuration for each of the possible values (from 1 neighbor to all the 16 possible neighbors). The results showed convergence in the optima found when a number of 8 neighbors are evaluated in each iteration, and this was the value selected for the experiments.

5.2 Simulation Modeling implementation

Similar as in [7,14,19], two discrete-event simulation hypothetical models were developed using R's Simmer library [23] to test the proposed framework. Both generic models share the same number of processes (four in a single-line layout), costs of parameters, and consider the same performance metric (the number of entities that exit the models). The first one, the main model, includes elements to evaluate variance given by complex processes. With this end, the main model was developed with shared resources for the processes, boredom rates for the entities waiting in a queue, and an optional process. The second model, the secondary one, aimed to represent a simpler system but with more variance, deleting all the complex elements of the main model.

The decision variables of the models and the optimization problem are given by the number of resources that each of the four processes has, and the size of the waiting queues for the two first processes, resulting in six decision variables. Considering a bit codification of three bits per decision variable, eight possible values were given for each decision variable from one to eight in the case of the number of resources and two to sixteen in the sizes of both queues. The resulting search space is defined by 262,144 possible configurations. For each model, a maximum number of runs of six was selected. This value was chosen considering a preliminary analysis of the performance of the dynamic runs technique for a sample of 50 random configurations. The results showed that the biggest increment in saved runs was obtained for a maximum number of 6 runs, hence this value was selected to evaluate appropriately this technique and limiting the computational costs of the case study.

5.3 Experimental Results

Simulation's metrics

To evaluate the statistical techniques in the framework two metrics were proposed: the number of replications saved by the dynamic runs technique and the variance reduction caused by CRN and AV.

In the case of the number of replications saved using dynamic runs a sample of 50 different configurations were evaluated in the main simulation model. For a maximum number of replications of six, approximately a 29% reduction of executed runs was obtained. An analysis of different values for the maximum number of replications was conducted showing that the reduction of runs increases using larger maximum replications values for the model. The results are shown in Figure 2.

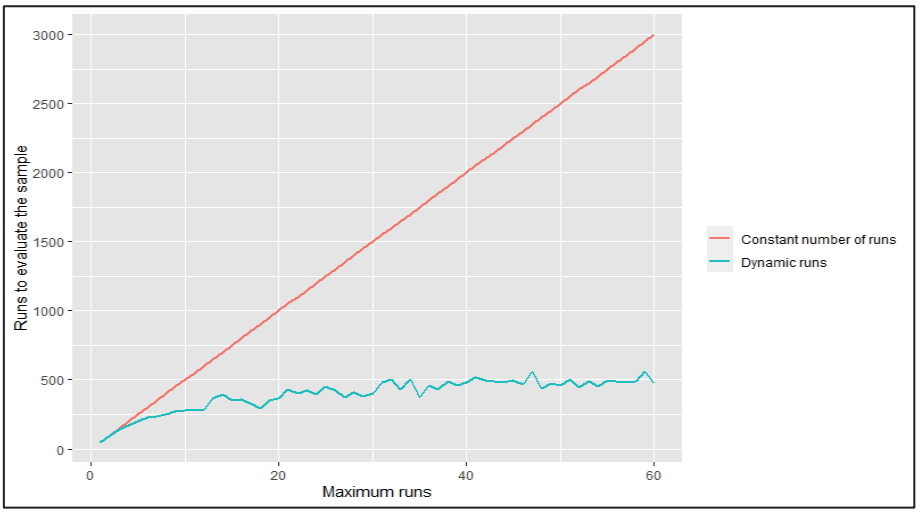

Fig. 2. Executed runs for the chosen sample using dynamic runs

To evaluate the variance reductions techniques, two metrics are defined based on Mawlana and Hammad [15] as described in Equations 7 and 8, which evaluate CRN and AV respectively

$$\Delta \sum_{i,j} S_{i,j}^2 = \frac{\sum_{i,j} S_{i,j\,IR}^2 - \sum_{i,j} S_{i,j\,CRN}^2}{\sum_{i,j} S_{i,j\,IR}^2} \tag{7}$$

$$\Delta \sum_{i} S_{i}^2 = \frac{\sum_{i} S_{i\,IR}^2 - \sum_{i} S_{i\,AV}^2}{\sum_{i,j} S_{i\,IR}^2} \tag{8}$$

where i and j are configurations of the search space, $S_{i,j\,IR}^2$ and $S_{i,j\,CRN}^2$ are the variances of the differences between configurations using independent runs (IR) and CRN respectively, $S_{i\,IR}^2$ and $S_{i\,AV}^2$ are the variances between runs of one configuration using independent runs and AV, respectively.

For the evaluation of the metrics shown in Equation 7 and 8, samples of 45 differences between random configurations and 50 random configurations were tested in the main model. The variance reduction of the differences between configurations caused by CRN was 68.33%. On the other side, the variance reduction of the runs of the configurations obtained using AV was 63.66%.

Optimization metrics

For the preliminary experimentation performed, a total number of 24 iterations of each heuristics were executed, and a limitation of simulation runs was chosen for the analysis. The first approach for the post-optimization phase in the methodology is the graphical analysis. This step is necessary for a complete study of the performance of the techniques and heuristics. Figures 3 and 4 show the results of the found optima by

each heuristic given a certain budget of simulation runs for the main model and the secondary model respectively and the corresponding confidence intervals.

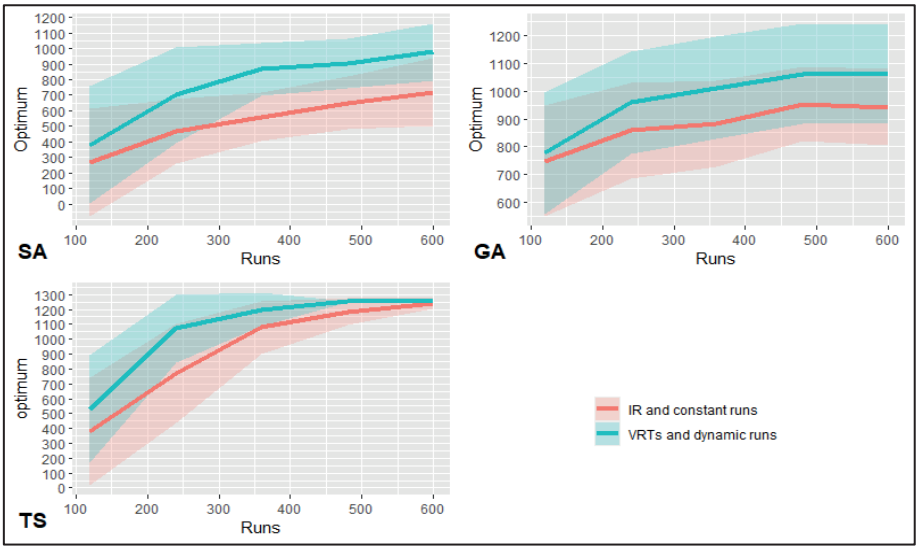

Fig. 3. Reported optimums by each heuristic in the main model

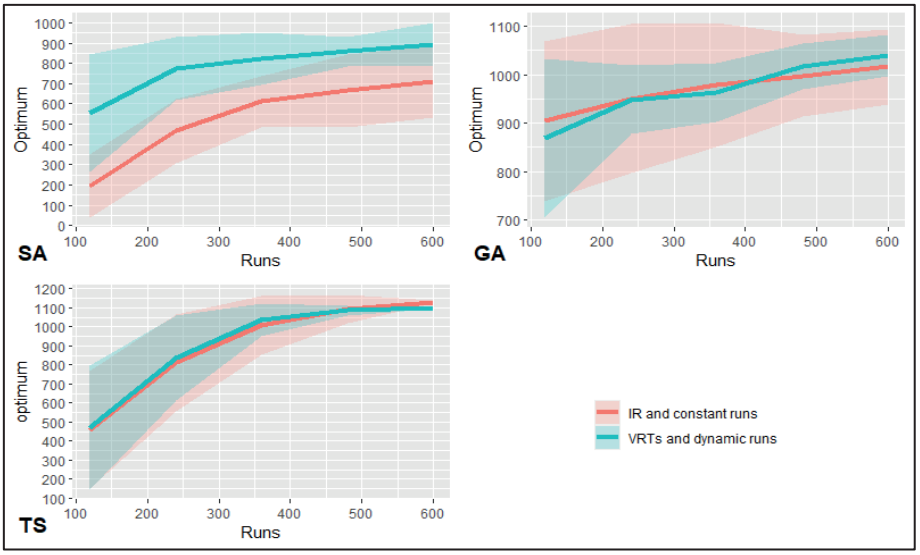

Fig. 4. Reported optimums by each heuristic in the secondary model

Figure 3 and 4 show important improvements on the reported optimums by each heuristic among all the different values of replications, especially for the results of simulated annealing. These results are confirmed by the implemented statistical tests

included in the post-optimization phase. For these tests and the remaining analysis of this section, a fixed budget of 600 and 500 runs is determined for the main and secondary models, considering that none of the metaheuristics have converged to a result with these budgets.

In line with the graphical results obtained, the metaheuristic that achieved the biggest improvements with the statistical techniques was the simulated annealing, that obtained gains of 40.13% and 28.96% in the reported optimums for the main and secondary models respectively. The genetic algorithms also reported important gains from the statistical techniques given by an improvement of 14.93% and 2.05% of the reported optimums for the main and secondary models. Finally, because of the chosen budgets (given by the convergence of the algorithm), the tabu search didn't report significant differences in the performance using the techniques. Nevertheless, the results shown in Figure 3 reports important gains for this metaheuristic with different budgets.

To analyze the effects of the interactions between each of the implemented methods, a mixed-level factorial design of experiments is proposed, where four factors are defined: the heuristic implemented and the use of CRN, AV and DR. Figures 5 and 6 show the results of the interactions that this experimental design obtained for the main model and the secondary model respectively.

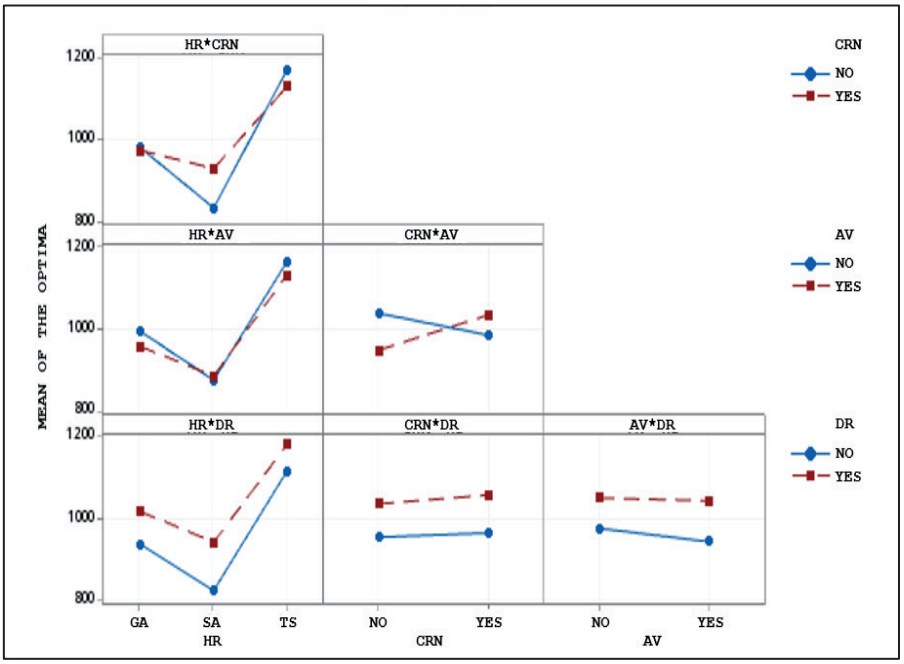

Fig. 5. Interactions of the results of the main model

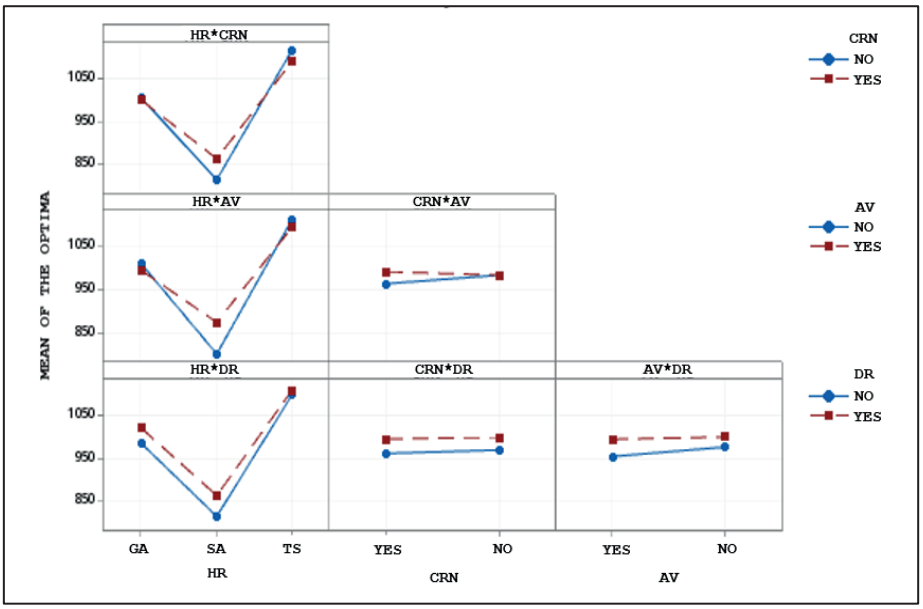

Fig. 6. Interactions of the results of the secondary model

For both models, the significant main effects are the heuristic of choice and the use of dynamic runs. These results show that the heuristic selected is still the most important decision when solving this kind of optimization problem. Also, the use of dynamic runs yields important improvements on the reported optimums.

On the other hand, for the main model, the significant interactions (shown in Figure 5) are CRN*AV, CRN*AV*DR, and HR*CRN*AV. These interactions show inconsistent behavior that can be explained by the unwanted correlations produced by the combination of CRN and AV, as shown by Kleijnen [12]. Also, the significance of the interaction HR*CRN*AV can be explained by the great influence of VRTs on the simulated annealing metaheuristic.

For the secondary model interactions (shown in Figure 6), the effects of HR*CRN*AV, HR*AV, and HR*CRN are significant. The effect of HR*CRN*AV can be explained by the same reason for the results of the main model. On the other hand, the significance of HR*AV and HR*CRN is produced by the benefits that simulated annealing obtain from the VRTs under a scenario with more variance as the secondary model.

6 Conclusions and recommendations for further research

The objective of this work is to propose a framework that analyzes, explores and improves the results of simulation-optimization heuristics using statistical techniques that complement traditional methods. The preliminary experimental results of the

implementation of two simulation models yielded important improvements for all the three heuristics selected.

Accordingly, the dynamic runs resulted the technique that provided better results in terms of the performance of the three algorithms. On the other hand, the obtained results led to the conclusion that a post-optimization analysis is required for the simultaneous application of the two variance reduction techniques. The inconsistent results of the combination of CRN and AV can even harm the search of local optima in some cases. In line with Anderson et al. [2] and Law and Kelton [13], variance reduction techniques are difficult to use due to the lack of understanding of the analysts who implement the simulation-optimization models and always require an effort to at least understand them.

These facts may discourage the use of variance reduction techniques. Nevertheless, due to the positive results obtained in this preliminary testing, independent use of only CRN or only AV may enhance the performance of each heuristic, especially in noise-sensitive heuristics such as simulated annealing, that don't operate with multiple candidate configurations at a time (like genetic algorithms or tabu search).

The work presented in this manuscript provides a first step to define a simulation-optimization framework, contributing to filling a gap that the existing literature [2] fails to address, by exploring the independent effects of each technique and the interactions between them that influence the performance of the different metaheuristics.

For further research, we recommend conducting a complete experimentation, based on the preliminary results obtained that may allow to evaluate different design settings of the metaheuristics, including tunning mechanisms of the control parameters. We also recommend considering hybrid designs of the algorithms due to the advantages that for example tabu search has, and the performance that a low temperature simulated annealing can achieve with variance reduction techniques. Also, the application of the proposed framework in specific decision planning problems that arise from real-world problems is suggested.

Abstract. Milk-run, a cyclic material delivering system, aims to increase the efficiency of transportation and supply chain based on lean logistics perspective. There are two kinds of milk-run systems as supplier and in-plant milk-run system in the literature. In-plant milk-run system that has growing appeals with Industry 4.0 concept, is applied to manage the process of delivering materials from warehouse to assembly stations in plants. This system can be implemented using Autonomous Vehicles (AV), which provide automated materials handling. However, a challenging problem arises in determining milk-run routes and periods for each AV, simultaneously. Besides, this problem becomes even harder in the presence of assembly stations with buffer stock constraint and requiring more than one commodity (multi-commodity). Since this problem is quite difficult to handle with exact solution methods, this problem is tackled here by using Simulated Annealing algorithm. To evaluate the performance of the proposed algorithm, we carry out experiments using a range of test problems. The computational results indicate that the suggested algorithm is efficient to obtain both milk-run routes and periods for each AV in reasonable computation times.

Keywords: Autonomous Vehicles, In-Plant Milk-Run System, Buffer Stock Area, Multi-commodity, Simulated Annealing Algorithm.

1 Introduction

Over the past decades, competition among companies around the world has become increasing. To survive in this competition environment, material handling system is one of the most important issue that should be well managed for companies. Some studies have revealed that it can account for 30-75% of the total cost and a well operated material handling system can reduce plant's operating cost by 15-30% [1]. Moreover, efficient material handling system ensures on time delivery, which is a key factor in the implementation of a lean logistics. It is a logistics application in lean manufacturing environment and provides the delivery of the products at the right time to the right place, effectively [2]. The implementation of lean logistics provides some benefits such

as balancing production line, reduction of stock levels and elimination of delays in the logistics process [3].

Lean logistics activities consist of 3 parts such as in-bound, out-bound and in-plant logistics [4]. While in-plant logistics deals with logistics in the factory, in-bound and out-bound logistics deal with obtaining raw materials and delivering goods to the customer, respectively [5]. These three types of logistics affect each other implicitly and one problem in any of them signify that there will be a problem in the others. For this reason, the logistics process should be carried out in a good way at all levels, simultaneously.

There is a correlation between a just in time plan and a good logistics strategy [6]. For in-plant logistics just in time material supply is a vital issue, because early material supply causes inventory holding cost and late material supply causes stopping assembly lines due to the parts shortage [7]. Milk-Run system, cyclic goods taking, is able to reduce these kind of delays in manufacturing especially in assembly lines [8]. Indeed, milk-run system can also be considered as a special kind of Vehicle Routing Problem with Time Windows [9]. Since it is actually a lean logistics method, it is possible to be implemented for all three types of lean logistics. There are two different milk-run systems as supplier milk-run and in-plant milk-run system in the literature [4]. With the supplier milk-run system, goods are collected from external suppliers and delivered to a customer by following a predefined route [10, 11]. On the other hand, in-plant milk-run system helps to deliver materials from warehouse to assembly lines in plants in a cyclic manner. Moreover, implementation of this system to the factory, mass production is made, is appropriate because many different materials should be delivered to the assembly stations at certain periods [12]. Unlike supplier milk-run system, it is not affected by external factors such as weather conditions. Accordingly, schedules of in-plant milk-run system are more reliable and robust [4]. The objective of in-plant milk-run system can be defined as minimizing the total inventory holding and transportation cost to ensure no parts shortage will occur in assembly stations.

In plant Milk-Run systems has some certain advantages listed below [13];

- Improved performance of the supply chain and logistics because of effective transportation,
- Lower inventory and reduced maintenance costs,
- More effective use of buffer stock area,
- More appropriate and reliable delivery times,
- Increased capital turnovers,
- Increased flexibility in supplying the parts,
- Smooth and well-established logistic operations.

Choosing the right material handling equipment is essential to improve facility utilization, increase efficiency of material flow, reduce waste in plant and provide effective utilization of manpower [5, 14]. There is growing interest using automated material handling vehicles especially with the Industry 4.0 concept. In this sense, in-plant milk-

run system can be applied using Autonomous Vehicles (AV). Contrary to Automated Guided Vehicles (AGV), AV navigates autonomously in the environment without any limitations on the paths. Therefore, it is more convenient to use AV in flexible logistics system which should be used in just in time production.

In-plant milk-run system is applied to manage process of in-plant logistics. Operating this system effectively is important not only for minimizing material handling cost, but also for ensuring continuity of production process. Demands of the assembly stations have to be satisfied from warehouse using AV by taking into account paths and time scheduling without causing any parts shortage. Therefore, it is crucial to obtain well designed milk-run routes and periods for each AV. In the meantime, milk-run period affects delivery quantities of the assembly stations and this influences milk-run route construction process because vehicle capacity is fixed [15]. So, the problem of obtaining milk-run period and route should be handled together. In addition, milk-run routes and periods should be determined considering demands of the assembly stations, capacity of buffer stock area, the number of vehicles and their capacities.

This study is set out to explore the design of in-plant milk-run system. Milk-run routes and periods must be obtained simultaneously to operate system, effectively. Although they are common issues, the inherent difficulties make this problem tough. These are the presence of AV capacity, limited buffer stock area and assembly stations requiring multi-commodity goods. Accordingly, related problem can be explained as obtaining milk-run routes and periods for AVs with the minimum total transportation cost to satisfy the demand of assembly stations in a cyclic manner.

Our research aims at developing effective solution method for obtaining milk-run routes and periods simultaneously for AVs in-plant. With this aim in mind, a novel method which is based on Simulated Annealing algorithm has been designed to solve this challenging problem in reasonable computation times. The structure of the generic Simulated Annealing algorithm is enriched by various neighbor search procedures used in probabilistic manner. To evaluate the performance of the proposed method, we carry out experiments using generated test problems. The key contribution of this work is solution representation that provides all information about milk-run routes, periods and it enables exploring the solution space effectively. Another contribution is that proposed approach gets high quality solutions at reasonable computation times even for large-scale problems.

The rest of the papers is organized as follows. The relevant literature is reviewed in Section II. Section III describes the related problem and gives detailed information about the proposed method. Test problems and computational results are presented in Section IV. Finally, Section V concludes the paper and provides future researches.

2 Literature Review

There is an increased attention to in-plant milk-run system area. So, a significant variety of designs of this system is found in the literature. Here we will discuss the literature which is relevant to our approach.

The problem that has arisen in obtaining milk-run routes and periods in-plant has been handled by researchers in different ways. Some researchers suggested exact solution methods, others developed heuristic methods. Besides, good overviews of earlier works in milk-run logistics and in-plant milk-run system is presented by [11] and [12].

First of all, studies proposing the exact solution method has been examined. Akillioglu et al. [16] proposed a mixed integer mathematical model to obtain route and cycle time for in-plant milk-run system. The objectives of this model is to minimize total inventory and distribution costs. The results of the mathematical model are evaluated by using a simulation model. Kilic et al. [5] classified the milk-run distribution system and developed a mathematical model for each case. The objective function of proposed mathematical models is to minimize the number of vehicles and the total travelled distance in-plant milk-run system. The most important finding in this study is that using multiple routed milk-run trains are more advantageous than one routed milk-run trains. Similar work has also been pursued by Kilic and Durmusoglu [17] in which they focus on periodic material delivery in lean production environment. They proposed a mixed integer linear programming model to minimize transportation costs. Volling et al. [18] developed a combined inventory-transportation system with multi-product, multi-vehicle and stochastic demand. They proposed an exact decomposition approach to handle the related problem and reported that substantial gains are achieved by this approach. Emde and Gendreau [19] explored scheduling tow-train with predefined routes to feed parts to automotive assembly lines. They developed a mixed-integer mathematical model to minimize in-process inventory cost. A more efficient implementation for in-plant milk-run system has been proposed relatively recently by Satoglu and Sipahioglu [7]. Because, they proposed two different assignment based mathematical model for just in time material supply system of the assembly lines. One of the models doesn't guarantee obtaining the global optimum solution, but this model performs better performance with regard to computation time. Mao et al. [20] introduced "Milk-run routing problem with progress lane (MRPPL)" to the literature. This problem is about to collecting automobile parts by integrating the progress-lane into the corresponding vehicle routing problem. They proposed a mixed integer linear programming model for small scale problems. Buyukozkan et al. [21] focused on in-plant milk-run system application in white goods industry. To maintain the assembly lines' operations, they proposed a mathematical model for single-vehicle case milk-run system with predetermined periods. Buyukozkan and Satoglu [22] also proposed a mathematical model for multi-vehicle case milk-run system with predetermined cycle times. Sipahioglu and Altin [23] dealt with in-plant milk-run system with predetermined periods. They developed a new mixed integer mathematical model to obtain milk-run routes and periods for AGVs. This

model allows split deliveries for stations and increase vehicle capacity by adding trailers. Besides, the proposed model has less number of constraints comparing the others and quite short computational time to obtain the optimal solution.

Studies proposing the heuristic methods has been reported as follows. Golz et al. [24] explored just in time part supply system with predefined routes to minimize the required number of shuttle drivers. They developed a heuristic solution procedure consisting of two stage. Gyulai et al. [9] proposed an initial solution generation heuristics and a local search method to solve the vehicle routing problem to obtain routes for in-plant milk-run planning problem. Kilic and Durmusoglu [17] tackled periodic material delivery in lean production environment with a predefined route in equal cycle times. They proposed a heuristic method since the optimal solution could not be obtained when scale of the problem gets bigger. Fathi et al. [25] discussed the assembly line part feeding problem with predefined tours. They suggested a modified particle swarm optimization algorithm to solve two sub-problems which are tour scheduling and tow-train loading problems. Emde and Gendreau [19] also offered a decomposition heuristic to solve instances of realistic size in acceptable computation time for scheduling tow-train with predefined routes. Mao et al. [20] also proposed genetic algorithm to obtain trip routes to collect automobile parts within a reasonable computation time for large size instances. Buyukozkan et al. [21] focused on in-plant milk-run system with predetermined period, multi product and limited buffer stock area. They proposed matheuristic algorithm that solve the proposed single vehicle milk-run model iteratively for multi vehicle case. Buyukozkan and Satoglu [22] proposed artificial bee colony algorithm to solve large scale in-plant milk-run instances with predetermined cycle time, multi product, multi vehicle and limited buffer stock area.

It is clear that, previous works are aimed at obtaining milk-run routes and periods for vehicles to minimize total cost of in-plant logistics. It is understood from these studies that the related problem can be extended in terms of the problem size and computation times. On the other hand, a solution approach that enables obtaining milk-run routes and periods simultaneously for large scale problems will contribute to the literature. In this sense, we proposed Simulated Annealing algorithm for in-plant milk-run system with multi commodity, multi vehicle and limited buffer stock area.

3 Problem Definition and Proposed Method

Companies take care not to stop assembly stations due to the parts shortage and make an effort to ensure continuity of production in plant. Therefore, it is vital to satisfy demands of the assembly stations on time. Since different operations are carried out at each assembly stations, the material types and quantities required by the stations may differ from each other. Accordingly, assembly stations must be fed periodically by AVs to minimize total transportation costs. In this feeding process, routes and periods for AVs should be obtained in accordance with the following conditions and assumptions:

- Each route starts and ends at the depot.
- Each AV is operated at most only one route.

- Each station is visited only once.
- AVs are homogenous.
- Each assembly stations have only delivery demands.
- Demands of each station are known but varies with regard to milk-run period.
- Distances between assembly stations are known and used as a distance matrix.
- Unloading time at each station is limited to 0.5 minute.
- Speed of each vehicle is 10 meters per minute.
- There are limited and known buffer stock area for each station.
- Stations require different types of goods.

Taking into account all of these, it is necessary to determine milk-run routes and periods for each AGV in order to operate in-plant milk-run system. However, a challenging problem arises in determining milk-run routes and periods simultaneously. This problem is difficult to handle by exact solution method in reasonable computation times. Therefore, we have developed Simulated Annealing (SA) algorithm.

SA algorithm was proposed by Kirkpatrick et al. [26] and Černý [27] as a single solution based metaheuristic approach. SA is a stochastic neighborhood search method that imitates the physical annealing process where a solid is slowly cooled until the minimum energy state is achieved. Therefore, not only improving solutions are always accepted, but also non-improving (inferior) solutions can be accepted by acceptance probability of the Metropolis criterion. This acceptance probability function is the main mechanism of SA algorithm and prevents getting stuck into local optima [28]. Thus, this algorithm provides obtaining high quality solution in a reasonable computation time. Because of its simplicity and efficiency, SA algorithm has widely been applied to solve most of the combinatorial optimization problems.

In order to apply metaheuristic algorithm effectively, an appropriate solution representation structure should be used. It should be easy to generate new and feasible solutions from a current solution. Proposed solution representation is shown in Figure 1. It consists of positive and zero numbers. Positive numbers represent delivery customers and zero numbers indicate vehicles. So, this solution representation length is related to the number of customers and vehicles.

8	2	5	0	1	9	7	0	6	4	3

Fig. 1. An example of solution representation.

The main advantage of suggested method is the suggested solution representation. This representation provides all information about milk-run routes and periods that are vital to operate in-plant milk-run system, efficiently. Referring to Figure 1, it is clear that there are 9 customers and 3 vehicles. Milk-run routes for each vehicle are as follows; first route is 0-8-2-5-0, second route is 0-1-9-7-0 and third route is 0-6-4-3-0. On the other hand, milk-run periods are calculated taking into account trip time of route and unloading time at each station.

SA algorithm was modified to achieve high quality solutions by using different neighbor search operators. Four different search operators have been used such as swap, insert, 3-change and reverse. These operators have been used probabilistically with regard to the scale of the problem. For small scale problems (number of customer ≤ 45), only swap, insert and 3-change operators have been used with equal probability. On the other hand, for medium (number of customer ϵ [55, 95]) and large scale problems (number of customer ≥ 150), all operators have been used with equal probability. Moreover, the number of iteration has been used as a stopping criteria and geometric cooling schedule has been used in this algorithm.

These neighbor search operators are robust and ensure obtaining milk-run routes and periods in any case. For example, route and period information is obtained from the customer numbers that are among zero values in the neighbor solution obtained by swap operator. On the other hand, if there is no customer number among the zero values, then it is understood that one of the vehicles is not used. So, the presented method is capable of generating feasible neighbor solution at each iteration when capacity of AVs and buffer stock areas is ignored.

Capacity of AVs and buffer stock areas is allowed to be exceeded in order to take advantage of the information about different solutions. A penalty function has been proposed to prevent the capacity to be exceeded in the final obtained solution and it also makes exploring the solution space, extensively. Pseudo code of the developed algorithm is given below.

Pseudo Code of Proposed Simulated Annealing Algorithm

Definitions:

s: solution	$f(s_0)$: objective function value of the initial solution
s_0: initial solution	$f(s')$: objective function value of the neighbor solution
s': neighbor solution	
$f(s_{best})$: objective function value of the best obtained solution	
s_{best}: the best obtained solution	α: cooling rate
T_0: initial temperature	T: current temperature
P: penalty coefficient	e: Excess capacity value

Preliminary Step:

Generation of the initial solution (s0), calculate objective function (f(s0)
$s_{best} := s_0;\ f(s_{best}) := f(s_0);\ s := s_0;\ f(s) := f(s_0)$
Determine the initial temperature and cooling rate
$T := T_0;\ \propto = 0{,}99$
Determine neighbor search operators to be used based on the problem size.
Determine the number of iteration.
Determine stopping criteria for the algorithm.

```
Repeat
     Repeat
          Generate s′ neighbor solution randomly with one
of the swap, insert, 3-change and reverse operators
          Calculate f(s′) with penalty function
          f(s′): = f(s′) + (p ∗ e);
          Δ= f(s′) − f(s);
          If Δ≤ 0;
               Accept neighbor solution (s: = s′);
          Else;
               Generate random number u = (0,1);
               If u < e^(−Δ/T), accept neighbor solution (s: = s′);
          If f(s′) < f(s_best);
               The best obtained solution (s_best: = s′)
     Until (the number of iteration)
     Update temperature T: = T ∗∝
Until (Stopping Criteria Satisfied)
Return the best obtained solution and objective function
value s_best, f(s_best)
```

The success of the algorithm is discussed in following section on generated test problems.

4 Computational Results

Here we evaluate the performance of our approach by using test instances. Firstly, environment features and parameter values of the problem are explained in detail over a small size test instance. Afterwards, this problem was solved for different scenarios and the obtained results are presented. Finally, parameter values used in generating test problems, the proposed algorithm parameters and the obtained results are mentioned.

A visual representation of generated test instance having 15 assembly stations and 1 warehouse is shown in Figure 2. Different types of materials are available in the warehouse and homogenous Autonomous Vehicles operated to transport these materials to assembly stations are ready for use. Besides, vehicle roads in the facility are shown with dashed lines. It is important to note that material transfer is carried out without exceeding vehicle capacities and buffer stock capacities of assembly stations.

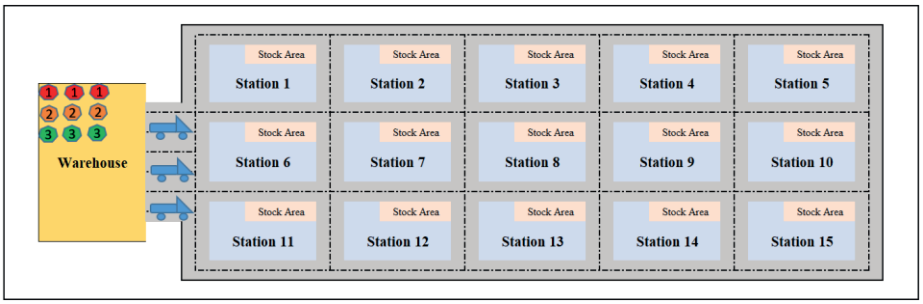

Fig. 2. Representation of facility layout.

There are 10 homogenous AVs available in this instance. Capacity of AVs is expressed on volume based. Therefore, the volumes of the materials to be transported should not be larger than the volume of the vehicle capacity. In addition, there is a fixed usage cost of AVs and unit material handling cost per distance covered. Capacity, fixed usage cost and unit material handling cost of these AVs are denoted in Table 1.

Table 1. Autonomous Vehicle Properties.

Number of AVs	**Capacity of AVs** (cm^3)	**Usage cost of AVs ($)**	**Unit material handling cost** $(\$/meter)$
10	1000	100	2

Assembly stations demand three different types of materials in this instance. Inventory holding cost that will occur if these materials are kept in buffer stock area and volume values of these materials are presented in Table 2. Additionally, the total inventory holding cost for each assembly station is calculated by multiplying half the amount of materials in the buffer stock area by the unit inventory holding cost.

Table 2. Material Properties.

Material Type	**Unit inventory holding cost** $(\$/cm^3)$	**Volume of a box of material** (cm^3)
Material 1	2	5
Material 2	5	10
Material 3	5	2

In this system, the demands of assembly stations must be satisfied on time and these stations must continue to operate by efficient transportation method. However, each assembly stations have a certain number of material demands in different periods based on their material consumption rates. Expressing station requests in different periods with this manner will cause complication. For this reason, 10 minutes' material demands of the assembly stations are calculated based on the original requests and stand-

ardization is provided in the feeding process with this way. Demands of assembly station for 10 minutes and capacity of buffer stock area for each station are shown in Table 3. It can be understood that the 3rd station requests 4 boxes of material-1, 7 boxes of material-2 and 3 boxes of material-3 every 10 minutes. These amounts are known but varies with regard to the obtained milk-run period. To illustrate, if the AV serving 3rd station has a period of 15 minutes, so 3rd station will demand 6 boxes of material-1, 10.5 boxes of material-2 and 4.5 boxes of material-3 every 15 minutes.

Table 3. Assembly Station Properties.

Assembly Station	**Capacity of buffer stock area (cm^3)**	**Demand (box / 10 min.)**		
		Material 1	**Material 2**	**Material 3**
1	750	3	3	2
2	750	9	6	2
3	750	4	7	3
4	750	4	1	2
5	750	3	7	3
6	750	7	8	0
7	750	7	0	2
8	750	4	0	0
9	750	2	1	1
10	750	5	5	1
11	750	3	2	6
12	750	7	3	7
13	750	8	3	7
14	750	4	4	0
15	750	7	0	1

The proposed algorithm was run for the test problem (scenario-1) whose characteristic is given above. In addition, 2 different scenarios have been created since it is worth testing how well the proposed algorithm performs in different conditions. These scenarios were generated by using different capacity values for AVs and buffer stock areas. Capacity of AV and capacity of buffer stock area were determined as 500 (cm^3), 375 (cm^3) in scenario-2 and as 250 (cm^3), 150 (cm^3) in scenario-3. So, it will be observed how the proposed algorithm will handle tight capacity constraints. The proposed SA algorithm has run 5 times for this problem and the best obtained results have denoted in Table 4. The parameters of the algorithm (initial temperature, final temperature, number of iteration at each temperature and cooling rate) were specified as $(T_0, T_f, I, \propto) = (75, 0.1, 100, 0.99)$.

Table 4. Results of the Test Problem.

Scenarios	# of Stations	# of AVs	Routes	Travel Times (min.)	Unloading Times (min.)	Periods (min.)	Total Cost ($)	Computation Times (second)
1	15	3	Route-1 (0-10-12-3-13-15-4-9-0)	17.9	3.5	21.4	1940.5	11.92
			Route-2 (0-2-8-1-0)	14.8	1.5	16.3		
			Route-3 (0-6-11-7-5-14-0)	19	2.5	21.5		
2	15	4	Route-1 (0-1-8-2-9-0)	11.8	2	13.8	2098.6	12.02
			Route-2 (0-5-13-4-15-0)	18.1	2	20.1		
			Route-3 (0-10-6-11-7-0)	13.3	2	15.3		
			Route-4 (0-3-12-14-0)	16.6	1.5	18.1		
3	15	7	Route-1 (0-13-15-0)	13.8	1	14.8	2943	12.04
			Route-2 (0-3-10-0)	11	1	12		
			Route-3 (0-8-2-9-0)	11.8	1.5	13.3		
			Route-4 (0-4-12-0)	17.4	1	18.4		
			Route-5 (0-1-11-7-0)	16.8	1.5	18.3		
			Route-6 (0-5-14-0)	11.9	1	12.9		
			Route-7 (0-6-0)	8.2	0.5	8.7		

Table 4 provides the computational results of the related test problem in terms of 3 scenarios. In order to minimize total transportation costs in each scenario, milk-run routes and periods for AVs were obtained simultaneously. Column 2 and column 3 gives information about the number of assembly stations and the number of AVs operated in each scenario. The milk-run routes obtained for AVs are demonstrated in column 4. In this column, while the warehouse is denoted by 0, the assembly stations are shown by their numbers. The 5^{th} and 6^{th} columns show the travel times and the total unloading times for the relevant route, respectively. In the 7th column, milk-run periods obtained for AVs are specified. Each milk-run period is achieved by summing travel time and unloading time of the relevant route. The obtained total cost values for each scenario are shown in column 8 and the last column contains computation times which are given in seconds.

From Table 4, it can be understood that there are 3 AVs to satisfy demands of 15 assembly stations in cyclic manner for scenario-1. First AV supplies material 10, 12, 3, 13, 15, 4, 9th stations every 21.4 minutes, second AV supplies material 2, 8, 1st stations every 16.3 minutes and third AV supplies material 6, 11, 7, 5, 14th stations every 21.5 minutes. Thus, considering all cost items, the total cost was obtained as 1940.5 for scenario-1.

There are several points to note concerning the computational results. While 3 AVs were used in scenario-1, 4 AVs in scenario-2 and 7 AVs in scenario-3 were used. Besides, when these three scenarios are compared, the minimum total cost value was obtained in scenario-1, on the other hand the maximum total cost value was obtained in

scenario-3. These implications represent the impact of tight capacity constraints. That is to say, as the capacity of AVs and buffer stock areas is decreased, the number of AV needed and the total cost values increase. Moreover, it is observed that the duration of milk-run periods is shortened with tight capacity constraints. In addition, it is seen that there is no significant difference between 3 different scenarios with regard to computation times.

Different scale of test problems was generated to demonstrate the effectiveness of the developed approach. 15 different test problems were generated and classified as small, medium and large scale. All the parameter values of these test problems were expressed in Table 5. Besides, the parameter values used in the SA algorithm are shown in Table 6.

Table 5. Test Problem Parameter Values.

Parameters	**Small scale problems**	**Medium scale problems**	**Large scale problems**
# of AVs	10	15	50
# of Assembly stations	[10, 45]	[55, 95]	[150, 500]
Capacity of AVs (cm^3)	1000	5000	40000
Capacity of buffer stock area (cm^3)	750	1500	10000
Usage cost of AVs ($)	100	300	500
Unit material handling cost ($/meter)	2	3	5
Distance matrix	uniform(5,100)	uniform(5,100)	uniform(5,100)
# of Material types	uniform(2,5)	uniform(5,10)	uniform(10,20)
Material demands of stations (box / 10 min.)	uniform(0,10)	uniform(0,10)	uniform(0,10)
Volume of a box of material (cm^3)	uniform(2,20)	uniform(2,20)	uniform(2,20)
Inventory holding cost ($/$cm^3$)	uniform(1,5)	uniform(1,5)	uniform(1,5)

Table 6. SA Parameter Values.

	Small scale problems	**Medium scale problems**	**Large scale problems**
Initial temperature (T_0)	75	100	200
Final temperature (T_f)	0.1	0.1	0.1
Number of iteration (I)	100	150	200
Cooling rate ($\propto$)	0.99	0.99	0.99

The proposed algorithm was coded in Python 3.7 and run on an Intel Core i5 1.8 GHz PC with 8 GB memory. This algorithm has run 5 times for each test problem and the best obtained computational results have been presented in Table 7.

Table 7. Numerical Results of the Proposed Algorithm on the Test Problems.

Test Problem	**# of Stations**	**# of AVs**	**Total Cost ($)**	**Computation Times (second)**
S-1	10	3	1831	10
S-2	15	3	1940.53	12.5
S-3	25	5	3091.60	12.6
S-4	35	10	5463.46	25.7
S-5	45	9	5583.93	23.5
M-6	55	10	12509.91	84.2

M-10	95	15	26836	181.6
L-11	150	28	64697.27	1043
L-12	200	35	89325.96	1445.9
L-13	300	50	120402.67	1583.7
L-14	400	50	196526.37	2601.9
L-15	500	50	287402.60	3603.2

Numerical results of the different scale instances are summarized in Table 7 in terms of the number of assembly stations, the number of AVs operated, total cost and computation times. The first two columns of Table 7 contain information about test problems, such as instance name and the number of assembly stations. Third column shows the number of AVs used in test problems. Next column indicates the obtained total cost value and the last column includes computation times given in seconds. In these test problems, different milk-run routes and periods for AVs were obtained simultaneously in order to minimize total cost for in-plant milk-run system. So, the demands of the assembly stations have been satisfied by AVs in cyclic manner without violating ca-

pacity constraint for AVs and buffer stock areas. There is a significant positive correlation between problem size and the number of AVs and computation times needed. In other words, as the size of the problem increases, the number of AVs used and the computation times increases. However, even the L-15 problem which includes 500 assembly stations, 50 AVs and 20 different types of materials was solved in about 1 hour by our proposed algorithm. Therefore, it is seen that the proposed algorithm is able to produce good solutions for even large scale problems at reasonable computation times.

5 Conclusions

This study is set out to explore in-plant milk-run system with regard to material feeding process. The main problem encountered here is obtaining milk-run routes and periods simultaneously for AVs with the minimum total cost to satisfy the demand of assembly stations in a cyclic manner. Besides, this problem is quite difficult taking into account capacity of AV, limited buffer stock area and assembly stations demanding different types of materials. Simulated Annealing algorithm has been proposed to solve this challenging problem. Different neighbor search operators and penalty function have been used the structure of the SA algorithm. In addition, a well-designed solution representation, provides all information about milk-run routes and periods as well as it enables exploring the solution space effectively, has been proposed for SA algorithm. Computational experiment has been carried out for a range of the generated test problems. Computational results show that the proposed approach gets different milk-run routes and periods for AVs simultaneously at reasonable computation times even for large-scale problems. The proposed algorithm can handle even the L-15 test problem including 500 assembly stations, 50 AVs and 20 different types of materials in about 1 hour. Thus, it is seen that the proposed algorithm is a successful approach for in-plant milk-run system with multi commodity, multi vehicle and limited buffer stock area.

The key contributions of this work are the solution representation and obtaining high quality results at reasonable computation times. To the best of our knowledge, this is the first study to propose a metaheuristic algorithm for in-plant milk-run system with multi commodity, multi vehicle, limited buffer stock area and not using predetermined route and period.

In future work, it may be useful to study on a metaheuristic approach that allows split deliveries for assembly stations in-plant milk-run system and different metaheuristics can be used.

Resumen. El ruteo de vehículos es uno de los problemas más reconocidos de la literatura, su estudio ha tomado relevancia en los últimos años incluyendo diferentes variantes al problema, en este aporte se llevó a cabo la propuesta de un método de solución de dos fases para un problema de ruteo de vehículos teniendo en cuenta la frecuencia del servicio como característica principal y factores restrictivos de capacidad y ventanas de tiempo, a través de un modelo de programación entera mixta en la primera fase de asignación y la metaheurística de optimización por colonia de hormigas para la segunda fase de ruteo, acompañado de procedimientos locales y de enlace entre las fases, la implementación se hizo en el software Xpress Optimizer, finalmente para la verificación se realizaron pruebas con instancias de tamaños diferentes de la literatura que demuestran la aplicabilidad del método propuesto y sus ventajas sobre otros métodos de solución.

Palabras clave: Metaheurísticas, Métodos de dos fases, PVRP.

1 Introducción

Actualmente las organizaciones de toda índole se están enfrentando a un contexto de alta complejidad, globalización y constantes avances tecnológicos, por esta razón la distribución y transporte se han consolidado como procesos fundamentales dentro de las operaciones empresariales, llevar una adecuada gestión de estos procesos representa varias ventajas entre las cuales se encuentran la reducción del costo final de los bienes o servicios entre 10% y 20%, ofrecer un mayor nivel de servicio de acuerdo a los requerimientos de los clientes e incrementar la competitividad de las organizaciones. El ruteo de vehículos es una de las actividades realizadas con mayor frecuencia, sin embargo, para abordar este problema de naturaleza NP- Hard desde la academia, los métodos de solución exactos existentes implican límites de aplicación dependiendo del tamaño de los datos por aumento de la complejidad computacional, mientras que las heurísticas y metaheurísticas permiten obtener buenas soluciones a costos computacionales aceptables y permitir un manejo de mayor cantidad de datos.

2 Metodología y estado del arte

Para dar solución al problema planteado se realizó la construcción del estado del arte, enfocado al estudio de las diferentes variantes del problema y sus métodos de solución se evidencia la importancia de las heurísticas y metaheurísticas poblacionales, así como la necesidad de orientar el estudio del problema incluyendo la periodicidad como generalización del problema de ruteo de vehículos, se destacan los aportes de [1], [2], [3], [4] y [5]. Posteriormente se realizó un análisis de los métodos de solución heurísticos y metaheurísticos, correspondientes a la optimización por colonia de hormigas y heurísticas locales enfocadas al cumplimiento de los factores restrictivos, las cuales fueron implementadas a través del desarrollo de un algoritmo en el software utilizado. Se tuvieron en cuenta medidas de desempeño para determinar la eficiencia del modelo a través del análisis con instancias reconocidas de la literatura realizando pruebas comparativas con un método de iterativo de dos fases [6] el cual aplica métodos exactos a cada una de las fases para abordar el problema de ruteo de vehículos descrito anteriormente.

3 Algoritmo propuesto

El algoritmo desarrollado comprende dos fases, las cuales son ejecutadas de forma iterativa y enlazadas con dos criterios, ilustradas en la **Fig. 1** y estas son:

3.1 Fase de asignación

La fase número uno corresponde a un modelo de asignación, se utilizan técnicas de optimización a través de programación entera mixta para resolver una programación de visitas requeridas a cada uno de los clientes durante un horizonte de planeación definido, donde se busca reducir el costo de visita total, teniendo en cuenta aspectos como la demanda, la asignación de clientes a cada periodo del horizonte según la frecuencia mínima definida y las unidades faltantes o en exceso, estas últimas si así se requiere pueden ser asignadas a un día ficticio; si existe factibilidad, este modelo proporciona la información de entrada de la fase número dos, particularmente es exportada la información relacionada con los clientes asignados para cada uno de los días.

3.2 Fase de ruteo

Es comprendido un procedimiento de clustering utilizando el algoritmo de K-means modificado sobre la inicialización para facilitar la adecuación de los datos previa la entrada al ruteo, el cual recibe como información de entrada las coordenadas y ventanas de tiempo de cada cliente así como los clientes agrupados con la flota de vehículos disponible, posteriormente se realiza la ordenación respecto a las ventanas de tiempo de apertura de los clientes conformados en cada clúster; el algoritmo de ruteo funciona iterativamente dentro del horizonte de planeación (HP), la ruta es formada a través de etapas con procedimientos inspirados en el comportamiento de las hormigas dentro de una colonia, teniendo en cuenta la aleatoriedad y las heurísticas locales donde en forma

conjunta determinan los valores de probabilidad por arco con el propósito de cumplir con cada una de las ventanas de tiempo, teniendo como resultado la obtención de la mejor ruta según los factores restrictivos, una vez es construida la mejor ruta por hormiga e iteración, se evalúa la factibilidad, en caso de que exista infactibilidad durante alguno de los días del horizonte de planeación será ejecutado el criterio de salida y en caso de que esto ocurra en el día ficticio es ejecutado el criterio del inventario final.

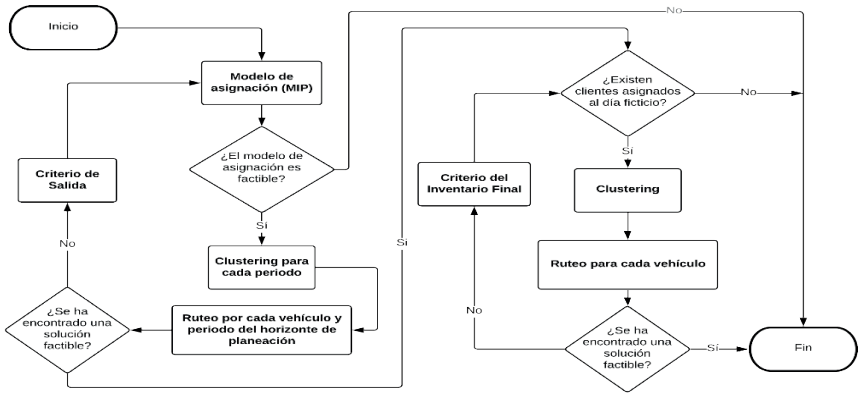

Fig. 1. Diagrama de flujo del método iterativo de dos fases propuesto. Fuente: Autores

3.3 Criterios de salida y de inventario final

Estos procedimientos conectan las fases, identificando los clientes que puedan influir en la infactibilidad de la ruta de algún vehículo durante un periodo donde no se encontró una solución factible, se penaliza el costo de visita del cliente identificado como problemático con el objetivo de que no sea asignado al día donde existió infactibilidad para el caso del criterio de salida, el segundo caso se ejecuta cuando existe una asignación sobre un periodo ficticio adicional al horizonte de planeación y este sea infactible.

4 Análisis de resultados

Se realizó una experimentación entorno a los parámetros del modelo de colonia de hormigas con ventanas de tiempo, determinando la combinación a utilizar dentro del modelo. Los valores a seleccionar de cada parámetro se basan en un diseño de experimentos realizado por [7], se presentan conjuntos de parámetros sobre los cuales se dan dieciséis (16) combinaciones para cada parámetro, ejecutando cinco (5) corridas para cada combinación. Se tuvieron en cuenta dos versiones del modelo propuesto, que se diferencian en el método de inicialización del algoritmo de clusterización, con esto se realizaron un total de 1120 pruebas. La verificación del modelo consta de un análisis con las instancias de Solomon (1987), con conjuntos de 25, 50 y 100 clientes, para el primer tamaño se obtuvo que un 60% de las instancias alcanzó la solución dada por el modelo base de comparación de [6], mientras que en los demás conjuntos de clientes se encuen-

tra que el 70% de las instancias alcanza una solución factible, condicionada a la formación de los clústeres, también se encuentra que se presenta un aumento del tiempo computacional relacionado con el aumento del número de hormigas e iteraciones para garantizar la convergencia del método a una solución factible tras aumentar el tamaño de clientes por visitar.

5 Conclusiones

Dentro de los hallazgos del modelo se aprecia el cumplimiento satisfactorio del algoritmo para dar solución al problema planteado utilizando heurísticas y metaheurísticas y la ventaja que representa para resolver problemas tipo NP-Hard, es notable que el cumplimiento de los factores restrictivos se da por el uso de heurísticas locales y procedimientos de mejora. Se identificó que la aplicación de un algoritmo de clusterización más robusto incrementaría el desempeño del algoritmo en términos de ocurrencia a una solución factible, adicionalmente, criterios que identifiquen diferentes condiciones de infactibilidad existentes dentro del este tipo de problemas. Finalmente es destacable que este tipo de algoritmos representan una complejidad computacional inferior a la obtenida por los modelos de optimización para abordar el problema de ruteo de vehículos y sus posibles variantes, por tanto la cantidad de clientes a considerar está sujeta a la disponibilidad de una licencia o software que soporte el volumen de datos.

Resumen.
La logística de aprovisionamiento es un factor clave para las organizaciones, esta comprende políticas de compra, gestión de transporte y distribución, diseño de almacenes, gestión de inventarios, entre otras. Cuando los miembros de una cadena de suministro realizan esfuerzos de cooperación con un objetivo en común, la logística Milk Run ofrece una alternativa para manejar el suministro de las materias primas/insumos para esto es necesario establecer una buena programación de las rutas que permitan mejorar la eficiencia en términos de costos y utilización del vehículo sujeto a los horarios establecidos por los proveedores. Esto se puede modelar mediante el problema de ruteo de vehículos Milk Run con ventanas de tiempo. Este problema es de tipo NP-Hard ya que al aumentar el número de pedidos a recoger y estar sujeto a las ventanas de tiempo aumenta la complejidad computacional, por tal razón es necesario el desarrollo de Metaheurísticas para su solución. En la presente investigación se propone un Algoritmo de Búsqueda Tabú. Se adaptaron instancias de la literatura logrando buenos resultados.

Keywords: Búsqueda Tabú, Logística Milk Run, Ruteo de vehículo, Ventana de tiempo.

1 Introducción

Si no se maneja bien la logística de entrada de una fábrica puede causar muchos desperdicios, como tiempo de espera y costos excesivos. Tiempo de espera por falta de materia prima. Costos excesivos, en términos de mantenimiento de inventario por poseer altos niveles de inventarios de materiales y en costos de transporte, por una deficiente asignación de los vehículos y las rutas generadas, estos costos de transporte representan una parte significativa (a menudo entre un tercio y dos tercios) del costo logístico en varias industrias [1]. Por ejemplo, en Colombia el costo de transporte representa entre el 46.2% de los costos logísticos en el sector industrial [2]

Así mismo, puede generar interrupciones en la línea de producción o pérdida de materia prima debido a mayor tiempo de transporte y almacenamiento desde los proveedores al fabricante.

Una alternativa para sincronizar los procesos de transporte y adquisición de materia primas/materiales con el proceso de producción del fabricante ha sido implementar la logística Milk Run que se fundamenta en los principios de producción ajustada. La idea es definir rutas estándar, que se repiten de forma regular (por ejemplo, diariamente o dos veces por semana) para un ciclo de planificación definido (por ejemplo, 3 semanas). Cada ruta estándar consolida las cantidades de reabastecimiento de un grupo de proveedores en una región geográficamente concentrada y define un programa de recolección periódico para cada proveedor [3].

Una cuestión fundamental en el estudio de la logística Milk Run es la definición de la ruta estándar. Dado que el modelo de decisión de ruta se vuelve complejo al aumentar el número de proveedores, tipo de vehículos y la capacidad limitada de los mismos traerá una mayor cantidad de variables de decisión.

Para enfrentar este desafío se ha abordado esta situación mediante el problema de ruteo de vehículos (VRP) en dos variantes: el primero, problema de ruteo de vehículos Milk Run (MRVRP) y el segundo, el problema de ruteo de vehículos Milk Run con ventanas de tiempo (MRVRPTW). La diferencia radica en la inclusión de la disponibilidad horaria de los proveedores para poder cumplir con el plan de producción del fabricante. Estos problemas son de naturaleza Np-Hard, por tal motivo han implementado diferentes metaheurísticas para su solución tales como Algoritmo Genético (GA), Algoritmo de Colonia de Hormigas (ACO) o Algoritmo de ahorros de Clark y Wright.

Sin embargo, no se ha investigado en el desarrollo de un algoritmo de Búsqueda Tabú que utilice la heurística del barrido para obtener la solución inicial. Entonces con el fin de proponer una alternativa de solución diferente a las encontradas en la literatura, se propone un Algoritmo de Búsqueda Tabú para dar solución al problema de ruteo de vehículos Milk Run con ventanas de tiempo (MRVRPTW) cuyo objetivo es minimizar costos.

Se utilizaron instancias sintéticas entonces se recomienda evaluarlos con datos reales. Esta investigación contribuye a soportar una de las principales decisiones del diseño Milk Run, la cual es el ruteo de los vehículos porque si existe una planificación adecuada del ruteo de vehículo contribuye a la eficiencia de la operación logística. Adicionalmente, aporta en mejorar la calidad del diseño de las rutas al reducir el tiempo computacional mediante un método alternativo como lo es el Algoritmo de Búsqueda Tabú.

El algoritmo desarrollado se puede implementar en el área de la logística de entrada de cadenas de suministro sincronizadas dado que se necesita una estrecha relación entre proveedores y fabricante. Los proveedores deben ser de alto valor económico para el fabricante y así mismo que los proveedores sean cercanos entre sí. Dentro de las características del fabricante se resalta que aplica una producción lean y necesite suministro de lotes pequeños con alta frecuencia. El resto del artículo está organizado de la siguiente manera: Sección 2 se presentan los antecedentes presenta la formulación del problema con los antecedentes. Sección 3 la definición del problema, el modelo

matemático y el diseño del Algoritmo de Búsqueda Tabú. Los resultados y su respectivo análisis en la Sección 5 , y finalmente, se presentan las conclusiones.

2 Revisión de Literatura

Mediante la revisión se identificó que el concepto Milk Run es utilizado para describir diferentes situaciones en las cuales ciertas características son más enfatizadas que otras. Las características a las que se hace alusión son las siguientes (1) Milk Runs son rutas fijas con recogidas fijas y franjas horarias de entrega (y volúmenes fijos) los cuales son ejecutados de acuerdo con un ciclo fijo. (2) En Milk Run, LTL de más de un proveedor son consolidados para poder aumentar la frecuencia de envío individual en comparación a ejecutar el transporte directo para cada uno de ellos. (3) Milk Runs son recorridos redondos en los que se intercambian contenedores retornables llenos y vacíos en una proporción de 1: 1. [aclarar bien esto]. (4) Milk runs son planeados por el destinatario [4] .

El problema del diseño Milk Run implica tres subproblemas: El primero, la asignación del concepto del transporte. Segundo, asignación de la frecuencia de reposición y tercero, la decisión del ciclo de programación del ciclo Milk Run. En la línea con el problema integrado [5], [1], [4]. Cuando un conjunto de proveedores decide utilizar el sistema de transporte Milk Run queda por abordar el segundo y tercer subproblema [3], [6], [7], [8], [9], [10]. Respecto al tercer subproblema, cuando se asume que el primer y segundo subproblema están resueltos, es decir, ya están asignados los proveedores al concepto de transporte Milk run y la decisión de frecuencia, cada cuanto se van a despachar los envíos. En este subproblema se necesita definir la secuencia de visitas de cada vehículo considerando la demanda, capacidad del vehículo y/o las restricciones de ventana de tiempo. En el contexto de la logística Milk Run tanto para la logística de entrada como la de salida se distinguen dos problemas principales, el primero es el problema de ruteo de vehículos Milk Run (MRVRP) y el segundo, el problema de ruteo de vehículos Milk Run con ventanas de tiempo (MRVRPTW).

El problema MRVRP ha sido abordado mediante metaheurísticas como Algoritmo Genético (GA), Algoritmo de Colonia de Hormigas (ACO) o Algoritmo de ahorros de Clark y Wright. En [11] propusieron un modelo matemático para el problema ruteo Milk-run con el fin de adaptarlo a las condiciones de un caso de estudio de la industria automotriz. El objetivo era reducir simultáneamente los costos de transporte e inventario abordando tres asuntos: utilizar diferentes proveedores para algunas piezas en particular, determinar la hora exacta en la que un proveedor enviaría las piezas y que un camión pueda trabajar en diferentes rutas en varios horarios. Resuelven el problema mediante el Algoritmo Genético y lo comparan con la estrategia actual obteniendo ahorros en el costo total. Un año más tarde [12] resuelven el problema anterior mediante optimización robusta. [13] propusieron un Algoritmo de Colonia de Hormigas (ACO) con mutación para el problema MRVRP con el objetivo de minimizar el tiempo de finalización más rápido, es decir, el tiempo de finalización de toda la tarea de

distribución es el tiempo de finalización del último vehículo, este lo aplicaron en el contexto de la logística de salida. En el área de la logística de distribución express [14] introdujeron el concepto Milk Run a la logística de distribución. Su objetivo fue minimizar la distancia transportada y los costos de transporte factores Utilizaron un Algoritmo de ahorros de Clark y Wright para resolver el problema. Aplicaron el modelo en una empresa privada de entrega urgente en China. De acuerdo con los resultados reducen el número de vehículos utilizados, la distancia total recorrida, mejoran el factor de carga del vehículo, todo lo anterior contribuye a disminuir el costo logístico.

Por otro lado, con la necesidad de incluir las ventanas de tiempo al contexto de la logística Milk Run varios autores han propuesto diferentes métodos para resolver el problema MRVRPTW tales como: Algoritmo de ahorros de Clark y Wright que combina una solución de dos rutas diferentes para formar una nueva ruta donde se validen los ahorros, Algoritmo de Dijkstra; metaheurísticas basadas en población como Algoritmo de Optimización por Enjambre de partículas (PSO), Algoritmo Genético (GA). [15] propusieron el modelo matemático para el problema MRVRPTW y lo abordaron mediante un Algoritmo de Optimización por enjambre de partículas (PSO).

En [16]proponen un sistema de ruteo de logística Milk Run justo a tiempo basado en el internet de las cosas. El sistema comprende dos subsistemas, es decir, el subsistema de ejecución y el subsistema de decisión. El primero captura las dinámicas del proceso de ejecución de la logística Milk Run y el segundo se encarga de la planificación de rutas iterativa en tiempo real basado en lo que le suministra el subsistema de ejecución, puede haber corrección de cantidad, ruta y vehículo. El modelo matemático de ruta tiene como función objetivo disminuir el costo fijo del vehículo, costo de viaje, una penalización por violar la restricción de carga del vehículo y la cuarta por violar las ventanas de tiempo duras. Diseñan un Algoritmo Genético mejorado y prueban la efectividad del ejemplo mediante un ejemplo de prueba.

[17] plantean una herramienta para la planeación y optimización de la logística Milk Run en el campo de los electrodomésticos. La planificación consiste en dos problemas, el problema de asignación que trata sobre la asignación de los proveedores a los recorridos y el problema de secuencia o enrutamiento para encontrar la secuencia óptima de clientes dentro de un recorrido determinado. En esta investigación dividieron los clientes en dos clústeres de acuerdo con la ubicación geográfica, lo aplicaron en un caso de estudio encontrando una disminución del 11.5% en costos de transporte comparado al enfoque sin aplicar Milk Run.

[18] analizan un caso de estudio en China, determinan los proveedores de transporte directo según la capacidad y para los demás proveedores adoptan el método de mayor frecuencia y lotes pequeños para recoger realizando la circulación, esta situación la modelan mediante el MRVRPTW. El objetivo es minimizar la distancia total recorrida. Diseñaron el Algoritmo de Clark y Wright. Seleccionaron al azar 15 proveedores del área de Shanghái para resolver la mejor ruta. Basados en los resultados mejora la eficiencia del vehículo, reduce el costo logístico y al mismo tiempo, el proveedor logístico y los proveedores logran una situación de beneficio mutuo.

[19] proponen un nuevo modelo matemático para el problema de programación y ruteo Milk Run considerando regulaciones presentes en Estados Unidos como el

máximo permitido de viajes y horas de trabajo. Lo resuelven mediante un Algoritmo Genético y lo aplican a un caso de 11 proveedores.

[20] involucran proveedores de primer y segundo nivel en el modelo logístico Milk Run con el objetivo de disminuir costos sujetos a una restricción de distancia máxima para el recorrido del vehículo y empleó un Algoritmo Genético para su solución. [21] abordaron el problema VRPTW con entrega Milk Run para la entrega de productos frescos y proponen el siguiente enfoque de solución: en primer lugar, obtienen la solución inicial factible con la ruta más corta mediante el Algoritmo de Dijkstra; en segundo lugar, mejoran la solución agregando las restricciones de capacidad de vehículos homogéneos y las ventanas de tiempo. El objetivo es minimizar el costo de la distancia visitada.

Desde el enfoque práctico la logística Milk Run se ha aplicado tanto para la logística de entrada como la logística de salida. En la logística de entrada principalmente en la industria automotriz para el suministro de auto partes en países como China [15], Tailandia [22], Portugal y China [23] , Indonesia [24], Vietnam [25]; en la industria de semiconductores [26]; electrodomésticos [17]. En la logística de distribución en la industria Express en China [14] porque el tiempo y costo son factores competitivos en esta industria, así mismo en la distribución de productos frescos como frutas y vegetales donde la reducción del costo y eficiencia en la utilización del vehículo es de especial interés [21].

3 Método

En esta sección, se presenta la descripción del problema, notación, supuestos y el modelo matemático propuesto por [15] base para la formulación del Algoritmo de Búsqueda Tabú.

3.1 Definición del problema

Se considera una cadena de suministro entre una fábrica y sus proveedores, la fábrica es la que genera la demanda y los proveedores de insumos/materiales están en el lado de la oferta. Esta cadena de suministro ha acordado trabajar bajo el concepto de transporte Milk Run, es decir, recogida y entrega de material en ciclos cerrados y repetitivos. Adicional a ellos se considera la existencia de un proveedor de logística de terceros (3PL). Este proveedor dispone de varios vehículos con la misma capacidad y es el responsable de organizar las rutas de tal manera que el número de vehículos sea mínimo y el costo total de transporte sea menor. Los proveedores solo están disponibles para entregar la mercancía en un horario específico.

El problema se rige bajo los siguientes supuestos:

(1) La demanda de cada proveedor, la distribución espacial de los proveedores y la capacidad de los vehículos del 3PL son conocidas y son iguales.
(2) Cada proveedor debe tener un solo vehículo para recoger los insumos/materiales, y existe una ventana de tiempo para atenderlo. Las ventanas

de tiempo son suaves, es decir, se permite violar las restricciones de las ventanas de tiempo, pero esto implica una penalización económica por incumplimiento que afecta la función de costo.

(3) La capacidad del 3PL es suficiente para cumplir con los requisitos.
(4) Se considera que la mercancía se transporte en pallets estandarizados.
(5) La velocidad media de un vehículo es constante y el tiempo medio de servicio en cada proveedor es igual.
(6) La matriz de distancia es simétrica.

3.2 Modelo matemático

Índices

i: nodo inicial i=1, 2,…, n (i=0 es para el comprador fábrica)
j: nodo final j=1, 2,…, n
k: vehículo k=1, 2,…, m

Parámetros

m: número total de vehículos
n: número total de proveedores
α: Costo de transporte por unidad de distancia
d_{ij}: Distancia entre el nodo i y el nodo j
v: Velocidad del camión
$\boldsymbol{\lambda}$: Costo por llegar antes de la ventana de tiempo.
μ: Costo por llegar después de la ventana de tiempo
V: Volumen máximo del camión
Q: Carga máxima del camión

q_i: Carga del nodo i.
u_i: Volumen demandado por el nodo i
t_{ij}: Tiempo de recorrido entre el nodo i y el nodo j
a_i: Tiempo más temprano para llegar al nodo i.
T_i : Tiempo de carga en el que el vehículo recibe las mercancías del proveedor i.
b_i: Tiempo máximo de llegada al nodo i.
s_i: Tiempo de llegada al nodo i
M: Número entero muy grande

Variables

$$x_{ijk} \begin{cases} 1, \text{si el vehículo k viaja del nodo i al nodo j} \\ 0, \text{lo contrario} \end{cases}$$

$$y_{ik} \begin{cases} 1, \text{si el vehículo k recoge en el punto i} \\ 0, \text{lo contrario} \end{cases}$$

Función Objetivo:

$$Min\ z = \sum_{i=0}^{n}\sum_{j=0}^{n}\sum_{k=1}^{m} C_{ij}x_{ijk} + \lambda\sum_{i=1}^{n} Max(a_i - s_i, 0) + \mu\sum_{i=1}^{n} Max(s_i - b_i, 0) \quad (1)$$

Restricciones

$$\sum_{i=0}^{n} q_i y_{ik} \leq Q \qquad k = 1, 2, \ldots, m \quad (2)$$

$$\sum_{i=0}^{n} u_i y_{ik} \leq V \qquad k = 1, 2, \ldots, m \quad (3)$$

$$\sum_{k=1}^{m} y_{ki} = 1 \qquad i = 1, 2, \ldots, n \quad (4)$$

$$\sum_{i=0}^{n} x_{ijk} = y_{jk} \qquad j = 0,1, 2, \ldots, n, k = 1, 2, \ldots, m \quad (5)$$

$$\sum_{j=0}^{n} x_{ijk} = y_{ik} \qquad i = 0,1, 2, \ldots, n, k = 1, 2, \ldots, m \quad (6)$$

$$x_{ijk} \in \{0,1\} \qquad i, j = 0,1, 2, \ldots, n, k = 1, 2, \ldots, m \quad (7)$$

$$y_{ki} \in \{0,1\} \qquad i, j = 0,1, 2, \ldots, n, k = 1, 2, \ldots, m \quad (8)$$

La función objetivo es minimizar el costo total. La primera parte de la función objetivo indica el **costo total por distancia recorrida, $C_{ij}=\alpha d_{ij}$**. La segunda y tercera parte son los costos de penalización por llegar antes o después de la ventana de tiempo respectivamente. Las ecuaciones (2) y (3) exigen que se deben cumplir las restricciones de capacidad en términos de carga y volumen; la ecuación (4) indica que cada proveedor solo puede ser tomado por un vehículo, la ecuación (5) y (6) indica que cada proveedor tiene el vehículo para recoger y solo se puede visitar una vez.

3.3 Algoritmo de Búsqueda Tabú

Se propone un Algoritmo de Búsqueda Tabú donde se utiliza la heurística del barrido para obtener la solución inicial. Búsqueda Tabú es un algoritmo de búsqueda local, se distingue de otros métodos de búsqueda local por el uso de memoria denominada Tabú donde almacenan las soluciones exploradas recientemente. El tiempo que un atributo permanece Tabú se llama tenencia y el estado Tabúes puede anularse si se cumplen ciertas condiciones. Esto se llama criterio de aspiración y ocurre, por ejemplo, cuando

una solución tabú es mejor que cualquier solución vista anteriormente. [Mejorar esta explicación]

La heurística del barrido tiene como objetivo crear clústeres de proveedores realizando un barrido de estos que permitan agrupar los proveedores más cercanos entre sí hasta incluir la mayor cantidad de proveedores posibles dentro de la ruta, para luego desarrollar la secuencia de las paradas dentro de las rutas.

3.3.1 Representación de la solución

Se utiliza un método de arreglo común para representar la solución tanto proveedores como fábrica, por ejemplo, existe 15 proveedores y 5 tipos de vehículos. "0-12-4-2-13-0-15-14-5-0-10-11-7-6-0-1-9-3-0-8-0", es la ruta inicial la cual consiste en cinco sub-líneas, "0-12-4-2-13-0", "0-15-14-5-0","0-10-11-7-6-0","0-1-9-3-0" y "0-8-0".

La dimensión del vector, D está relacionado con el número de vehículos K y los puntos, siendo D=K+L-1.

3.3.2 Generación del vector inicial o de la solución inicial

El vector inicial se genera a partir de una modificación al método del barrido, pues este empieza en la fábrica (nodo cero), luego busca el más próximo a este, analizando la carga, posteriormente se dirige al nodo más cercano de este último con su respectivo análisis de carga y se devuelve a la fábrica cuando no pueda captar más carga. La modificación busca que la ruta esté lo más cerca a la hora de llegada de cada nodo, por lo cual no se elige el más cercano, sino el que genere menos tiempo de perdida.

El vector inicial se genera a partir del método del barrido, la ruta comienza en la fábrica (nodo cero), luego busca el proveedor más cercano al nodo cero, este sería N1, siendo este el primero que visita el camión. Luego se procede a determinar el vector T_D mediante la ecuación (9), donde T es el tiempo que lleva el camión hasta la hora de salida del nodo anterior.

$$\mathrm{T_D} = \left(\frac{\mathrm{DIS}(N1,:)}{\mathrm{VP}}\right) + \mathrm{T} \tag{9}$$

Luego de determinar el T_D de la ecuación 11, se procede a restarlo con el vector HLL, generando un nuevo vector llamado T_1, luego se halla la posición del escalar más cercano a cero en el vector T_1, obteniendo el proveedor N2, siendo este el nodo siguiente a visitar.

Una vez determinado el segundo proveedor, se analiza la carga que está llevando el camión en (N2), y si esta es menor a la carga máxima permitida (CG) se procede a repetir el proceso mencionado en el párrafo anterior.

Cuando CG llega a ser mayor en el nodo Nn, el vector inicial (VI) se escribe de la siguiente manera: 0-NI-N2-***-$N_{(n-1)}$-0-Nn, luego se anexa un cero al final para que el último camión pueda retornar a la fábrica. Los nodos visitados van siendo eliminados en la matriz distancia, ventana de tiempo y vector carga para evitar que se llegue a

repetir en la fase del vector inicial. El pseudocódigo correspondiente a la generación del vector inicial se muestra en la Figura 1.

Algoritmo: Vector inicial
Entrada: Matriz distancias (DIS), parte inferior de la ventana de tiempo (HLL), parte superior de la ventana de tiempo (HS), vector carga o carga en cada nodo (CARGA) y carga máxima del camión (CG).
Salida: Vector inicial (VI)

Etapa 1. i=Número de nodos sin incluir el centro de acopio;
J=0;
VI=0;
Etapa 2. Repetir hasta i;
{
Etapa 3. Se determina el nodo más cercano al nodo N_{i-1}, obteniendo el nodo $N_{i;}$
Etapa 4. Guardar carga como J=J+CARGA(N_i);
Etapa 5. VI=[VI, N_i]
Etapa 6. Si CARGA ≥ CG, entonces
VI=[0, N1,…, 0, N_i]
}
Etapa 7. Parar y reportar VI=[VI, 0]

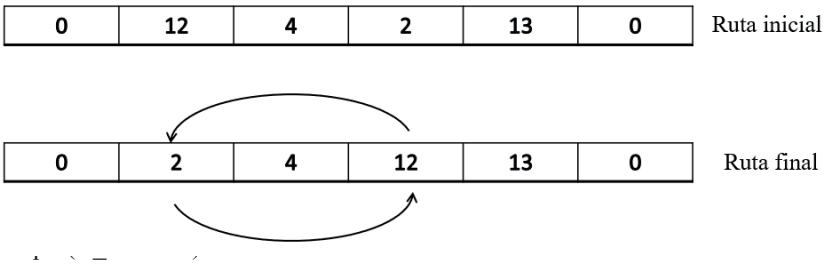

Figura 1. Vector Inicial

3.3.3 Evaluación de la solución

La función objetivo es la ecuación (1) la cual busca minimizar costo relacionado con transporte y tiempo de espera por llegar fuera de la ventana de tiempo.

El primer término de la ecuación (1), el costo total asociado a la distancia total recorrida se halla de la siguiente manera: primero se calcula la distancia total recorrida (J). El costo de transporte, C_TRANS se multiplica por la distancia total, DIS_T=DIS(1) +DIS(2)…DIS(n)).

El segundo y tercer término de la ecuación (1), el costo total asociado por llegar fuera de la ventana de tiempo. Se procede de la siguiente manera: asumiendo que el tiempo de carga es C. Se comienza determinando la distancia acumulada DIS_T=DIS(1)+C+DIS(2)+C, luego se analiza en el nodo N2 si la suma anterior está dentro de la ventana de tiempo, si se encuentra ahí, no hay costo asociado por llegar a deshora, no obstante, si esta fuera de la ventana de tiempo, se analiza si está por debajo o por encima de la ventana de tiempo, si está en el primer caso se guarda como VT_EARLY, si es el segundo caso, se guarda como VT_LATER, se repite el proceso para el nodo N3, comprendiendo que la distancia acumulada general se expresa de la siguiente manera: DIS_T=DIS(1)+DIS(2)+…+ DIS(n)+(n*C), donde n es el nodo que se está analizando sin contar la fábrica (nodo 0). El pseudocódigo se muestra en la Figura 2.

Salida: C_TOTAL.

Etapa 1. i=diámetro(VI)-2;
DIS_T=0;
H=0;
VT_EARLY=0;
VT_LATER=0;
Etapa 2. Repetir hasta i;
{
Etapa 3. Determinar DIS_T=DIS_T+ $DIS_{(i,i-1)}$;
Etapa 4. Hallar H=H+(J/VP);
Etapa 5. Si H < $HLL_{(i)}$, entonces VT_EARLY= VT_EARLY+H;
Else if Si H < $HS_{(i)}$, entonces VT_LATER = VT_LATER +H;
}
Etapa 7. Parar y reportar C_TOTAL=(DIS_T*C_TRANS)+(VT_EARLY*C_EARLY)+(VT_LATER*C_LATER);

Figura 2. Costo

3.4 Estructura de vecindario

Se utiliza una estructura de vecindario simple. En el vector no se modifica el primer y último nodo. Los vecinos se generan intercambiando las posiciones de dos nodos de una misma ruta (ver Figura 3).

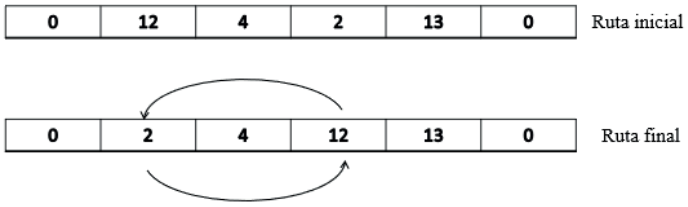

Figura 3. Vecindario generado en una ruta

Después de realizar el cambio se procede a analizar cada ruta, y aquellas que no cumplan la restricción de carga máxima, se transforma en 2 veces el valor máximo del vector de costo (C_ALL), garantizando así que no se pueda seleccionar como la solución de la iteración. Después se localiza el menor elemento (m) en el vector C_ALL sin incluir el primer elemento dado que este está asociado al vector inicial.

3.4.4 Lista Tabú

La Lista Tabú impide que se repita soluciones que permitirían salir de un óptimo local. Después de obtener la ruta que tenga el menor costo asociado, se guarda dicho vector VI_T(:,m) en la Lista Tabú. Los vectores que están en la Lista Tabú quedan prohibidos, sin embargo, para saber si el nuevo vector determinado está en la Lista Tabú, se procede a restar VI con cada vector de la Lista Tabú, si, y solo si el resultado es un vector de ceros, se puede asegurar que es el mismo, convirtiendo su costo asociado en 2 veces el valor máximo del C_ALL actual, garantizando así que no se pueda seleccionar ningún vector de la Lista Tabú, posterior a esto se procede a determinar el costo y localización del menor elemento en el vector C_ALL resultante (nuevo m) sin incluir al primer elemento. Dicha localización permite encontrar su respectiva ruta VI_T(:,(nuevo m)), siendo este el nuevo VI, este proceso se repite el número de iteraciones, i. . Cada ruta se va almacenando en una matriz llamada RUTA y el costo asociado en un vector llamado GRAF. Al final del proceso, se localiza el escalar más pequeño. pequeño en COSTO3 y su vector asociado en la matriz RUTA, siendo esta la mejor solución.

4 Resultados y análisis

Para validar el comportamiento del Algoritmo se utilizaron tres ejemplos. El primero, fue propuesto por Ma, y Wei, (2013). El segundo y tercero se generaron aleatoriamente a partir del primero, pero cambiándole la cantidad de proveedores, n, siendo 25 y 50 respectivamente. En la Tabla 1 se muestran las características de los ejemplos que permanecen constantes en los tres ejemplos tales como los costos de penalización por llegar fuera de la ventana de tiempo, costo de transporte y tiempo de servicio.
Tabla 1. Parámetros iguales en los tres ejemplos

Notaciones	Valores	Unidad
α	15	km/hora
$\boldsymbol{\lambda}$	12	yuanes/hora
μ	13	yuanes/hora
T_i	0.25	hora

En la Tabla 2 se muestran los parámetros que se generaron con distribución de probabilidad uniforme para el segundo y tercer ejemplo.

Tabla 2. Parámetros generados mediante distribución de probabilidad

Notaciones	Valores	Unidad
$\boldsymbol{\mu_i}$	[3, 14]	m^3
$\boldsymbol{a_i}$	[6.50, 12.50]	hora
$\boldsymbol{b_i}$	[7.7, 12.]	hora
X Y	[5, 65]	Km

En la Tabla 3 se muestran los parámetros que permanecieron iguales en el segundo y tercer ejemplo.

Tabla 3.Parámetros iguales en el segundo y tercer ejemplo

Notaciones	Valores	Unidad
V	60	m^3
v	60	Km/hora
$\boldsymbol{X_0, Y_0}$	[35, 35]	Km

Se realizaron unas pruebas iniciales y se determinaron que los parámetros del Algoritmo de Búsqueda Tabú para cada uno de los ejemplos tal como se muestra en la Tabla 4.

Tabla 4. Parámetros del Algoritmo de Búsqueda Tabú

Notaciones	Posiciones	Lista tabú	Iteraciones
Ejemplo 1	3-4	5	50
Ejemplo 2	3-4	5	50
Ejemplo 3	4-5	50	100

Se realizaron 10 corridas del Algoritmo de Búsqueda Tabú para cada ejemplo y a continuación se muestra la mejor solución encontrada.

A partir de los resultados presentados en la Tabla 5 se puede evidenciar como el porcentaje de utilización de vehículos es mayor cuando se aplica Búsqueda Tabú (TS) comparado al Algoritmo de Optimización por Enjambre de Partículas (PSO).

Tabla 5. Comparación entre el PSO y TS en términos de distancia y utilización.

Algoritmo	Vehículo	Ruta del vehículo	Distancia Total (Km)	Volumen (m^3)	% Utilización
PSO	1	0-13-15-0	61,59	23	77
	2	0-6-14-5-0	74,16	25	83
	3	0-2-8-7-11-10-0	117,95	30	100
	4	0-12-4-0	55,81	10	33
	5	0-3-9-1-0	69,38	17	57
TS	1	0-2-7-11-10-0	105,92	25	83
	2	0-4-15-14-0	101,98	29	97
	3	0-12-13-5-6-0	63,17	29	97
	4	0-1-9-3-0	70,40	27	90
	5	0-8-0	52,50	5	17

En la Tabla 6 se evidencia que, aunque existe una mayor distancia recorrida por el Algoritmo de Búsqueda Tabú el costo total es menor en comparación al Algoritmo PSO, este costo se logra con menos iteraciones del Algoritmo.

Tabla 6. Distancia y costo total

Algoritmos	Vehículos utilizados	Iteraciones	Distancia total de transporte (km)	Costo Total
PSO	5	50	378,89	7292,4
TS	5	140	393,97	6710,9

En la Tabla 7 se evidencia que existe mayor utilización de los vehículos cuando se tienen 50 proveedores.

Tabla 7. Resultados en términos de Distancia y utilización

Algoritmo	Vehículo	Ruta del vehículo	Distancia Total (Km)	Volumen (m^3)	% Utilización
Ejemplo 2	1	0-2-9-1-12-5-19-0	88,47	47	78
	2	0-13-3-24-22-14-8-4	80,39	58	97
	3	0-10-25-11-7-16-21-0	70,34	53	88
	4	0-15-6-17-18-23-0	68,61	58	97
	5	0-20-0	72,14	14	23
Ejemplo 3	1	0-3-28-25-16-48-0	85,84	12	20
	2	0-29-33-27-44-43-0	117,45	59	98
	3	0-50-6-21-45-32-38-0	136,16	50	83
	4	0-42-22-34-35-39-4-7-24-0	193,73	53	88
	5	0-40-10-8-9-13-26-36-41-0	183,73	45	75
	6	0-15-47-18-31-1-23-5-12-0	134,55	56	93
	7	0-37-2-14-19-14-49-0	113,94	57	95
	8	0-20-11-30-46-0	128,58	27	45

En la Tabla 8 se evidencia que para atender el doble de proveedores (n=50) solo se necesitaron tres vehículos adicionales comparado con el ejemplo 2 y así mismo el costo total se duplica.

Tabla 8. Distancia y costo total del ejemplo1 y ejemplo 3

Algoritmos	Vehículos utilizados	Distancia total de transporte (km)	Costo Total
Ejemplo 2	5	379,94	7445,92
Ejemplo 3	8	1093,98	20155,86

El problema de ruteo de vehículos Milk Run con ventanas de tiempo es complejo, de carácter NP-hard con amplias aplicaciones en la logística de abastecimiento entre un comprador y varios proveedores que mantienen una relación de cooperación en la cadena de suministro. La complejidad de instancias de mayor tamaño hace necesario implementar Metaheurísticas para proveer soluciones aproximadas en tiempo computacional razonable. Esta investigación propone un Algoritmo de Búsqueda Tabú para resolver MRVRPTW.

Para demostrar la efectividad del algoritmo se comparó con un problema propuesto por Ma, y Wei, (2013), el cual lo resolvían por el Algoritmo de Optimización por Enjambre de partículas, encontrando un costo menor 6710,9 y llegando al resultado en menos iteraciones, 50. Por otro lado, con el fin de analizar que pasaría si el número de proveedores aumenta, se encontró que el costo total con 25 proveedores es similar al de 15 pero cuando estos aumentan a 50 el costo total se duplica.

Este trabajo puede ser extendido al considerar emisiones de carbono en la función objetivo. Adicionalmente, considerar productos perecederos de vida útil fija para abordarlo en contexto de otros tipos de productos que sean de rápido movimiento como leche, productos agrícolas

Abstract. In this paper we introduce the presale strategy for nanostore fulfilment in emerging markets, explaining current strategies and proposing one where resources are routed simultaneously. We study this problem as an extension of the periodic vehicle routing problem with consistency and synchronization constraints. To solve this problem, we propose a Mixed Integer Linear Programming (MILP) formulation and a Metaheuristic Algorithm. We compare the MILP results against a two phase method that mimics current strategy and show a cost reduction of 3,04% in small instances (with 10 clients).

Keywords: periodic vehicle routing problem · Consistency · Synchronization · MILP · VND · nanostore delivery

1 Introduction

The most common scheme to retail products urban delivery in emerging markets is the traditional channel, composed by small business units, known as nanostores, operated by the same family members and usually with one single store [5]. These types of stores fit well to their consumers' needs because of their location and the small-scale product presentation which allows buying a daily portion [3]. The logistic process required to serve all those nanostores working under the traditional scheme is complex because there is a large number of delivery points and their small drop size. As an alternative to face this complex environment, companies operating in emerging markets resort to the so-called "presale" strategy where a seller visits each store to contact the store owner, take their orders, evaluate the product they offer, introduce sale promotions and guarantee the visibility of their products on the shelves [5]. To foster a good relationship between the seller and the store owner, it is important to keep the same seller attending each client. Usually, the delivery of the products ordered by the nanostore is carried the day after the preseller visit by a fleet of trucks. Current practices indicate that most of the times, those operations are managed

by different departments inside the enterprise: the sales department is in charge of the assignment and routing of the presellers whereas the logistics department is in charge of the trucks routing. This detachment may cause extra costs, feasibility problems and reprocessing of already made routes. Therefore, in this abstract, we propose to take both decisions simultaneously, avoiding those types of problems and finding solutions with minor cost.

To model the integrated planning of the presale and deliveries, we introduce the periodic vehicle routing problem with consistency and synchronization (ConSyncPVRP). This problem combines the attributes of the periodic vehicle routing problem (PVRP) [6], person-oriented consistency [8] and operation synchronization [4].

2 Problem Definition

The problem consists in deliver goods to a set of nanostores on a time horizon, where each one must be visited by two different resources: one preseller and one truck. Each customer has a given frequency (i.e., number of days that must be visited) and a demand for the whole planning period. Visiting days are grouped in so-called scenarios, (i.e, subsets of days), that serve to assign customers to delivery days. To assign a customer to a given scenario the number of visiting days of the scenario must be equal to the delivery frequency of the customer. The objective function of this problem is to minimize the total costs. There are two types of costs: fixed costs, which increase with every resource used, and variable costs, which increase with every distance unit traveled. The constraints we have to fulfill are: (i) every resource has to start and finish its trip at the depot, (ii) each nanostore should be assigned to a periodic scenario with the same number of visits than its required frequency, (iii) the preseller has to be consistent for every client, it means the presale visit has to be always made by the same preseller, (iv) there is operation synchronization between the resources: trucks must deliver to the nanostores the day after the presale visit, (v) the total load of every resource must not surpass its capacity, (vi) every resource must arrive at the depot before a daily time limit, (vii) Gavish and Graves sub-tour elimination constraints [1], and (viii) symmetry breaking constraints.

3 Solution Methods

To solve the ConSyncPVRP we propose two methods. The first one is a mathematical programming model whereas the second one is a three-phase metaheuristic to solve large instances.

MILP formulation: We built a mathematical programming model using a mixed integer linear programming (MILP) formulation in AIMMS software. In order

to test it, we adapted the instances of PVRP from [2] and solved 147 instances with 10 clients, 20 with 20 clients and 20 with 40 clients making a total of 187 instances. From the 187 instances only 84% were feasible. In a time lapse of an hour, we optimally solved all the 10-clients feasible instances but only 10% of the 20-clients feasible instances and none of the 40-clients feasible instances. As a benchmark, we compare the optimal solutions of the MILP formulation with 10-clients against a two stage approach that mimics the current practice by optimally solving the preseller decisions first and the vehicles decisions after. Our solution has an average cost decrease of 3,04%. The mean gap, the distance between the lower bound and the best integer solution, was 14,04% for the 20-clients instances and above 60% for the 40-clients instances. This results shows that the MILP formulation solve problem with less than 20 clients in a reasonable computational time and that the two-stage approach used by practitioners to tackle this problem currently leads to infeasibilities and extra costs.

Metaheuristic algorithm: For larger instances, we built a metaheuristic method with three components: a randomized constructive heuristic, a repairing heuristic and a variable neighborhood descend (VND) with five different neighborhoods, shown in Fig. 1. The randomized constructive heuristic builds a solution by randomly choosing a scenario and a pair of resources for each client (to insert the customer into their routes). This method assures the consistency in the preseller

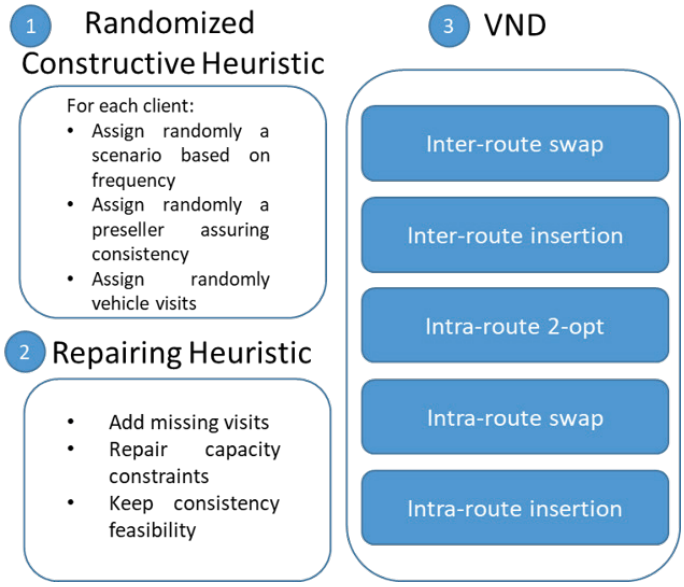

Fig. 1. Three-component metaheuristic representation

routing but some solutions could have feasibility problems with the capacity constraint of the vehicle. Then, the repairing heuristic tries to solve the infeasibility issue with two mechanisms. The first one examines which client has the least cost when changing its resources. If the possible resources are not available (all resources surpass their capacity), the second mechanism tries the least cost scenario change between all clients of the infeasible route. The repairing heuristic stops when all routes are feasible or after a given number of trials. If after a number of trials, the solution is still infeasible, it is discarded.

Finally, the VND improves the solution reducing the total cost. It contains five neighborhoods, the first two of them changes two routes at the same time meanwhile the last three operate over one route. The set of neighborhoods are: (i) inter-route swap of two customers, (ii) inter-route insertion of a customer, (iii) intra-route swap, (iv) intra-route insertion of a customer and (v) intra-route 2-opt [7]. This method is currently under development and computational testing. Results will be presented in the conference.

Resumen. El gran número de trabajos abordando el problema de scheduling en plantas batch deja en evidencia su importancia para lograr una operación eficiente de la planta, como así también su dificultad y el número de variantes que se pueden presentar. Usualmente el scheduling ha sido resuelto de manera simplificada, teniendo como datos el número y tamaño de batches (o lotes) necesarios para satisfacer la demanda. Más recientemente, han sido desarrollados modelos que resuelven simultáneamente el problema de batching, o sea determinar el número y tamaño de los lotes, y scheduling, logrando en general mejores soluciones. Sin embargo estos modelos son de una gran complejidad computacional, debido a su naturaleza combinatoria, por lo que lograr el desarrollo de modelos eficientes que permitan abordar problemas de gran tamaño continúa siendo un desafío. En este trabajo se presenta un novedoso modelo de programación mixta entera lineal (MILP) para la resolución simultánea del batching y scheduling en una planta batch multietapa, con unidades distintas operando en paralelo y fuera de fase en cada etapa.

Palabras clave: Planta batch multiproducto, Batching, Scheduling, Tiempos discretos.

1 Introducción

En la industria de procesos, tienen un rol destacado las plantas de producción batch debido a la flexibilidad de las mismas para procesar varios productos y en diferentes cantidades utilizando el mismo equipamiento. En este tipo de plantas el scheduling de la producción juega un papel fundamental para lograr un funcionamiento eficiente. Numerosos trabajos han abordado dicho problema durante las últimas tres décadas, cubriendo aspectos teóricos, diferentes representaciones y métodos de solución, cuyo alcance ha sido detallado en exhaustivos reviews ([1], [2], [3], [4]).

En ambientes de producción secuencial (plantas flowshop), la mayoría de los modelos presentados en la literatura resuelven en una primera etapa el problema de "batching", es decir, determinan el número y tamaño de los batches necesarios para satisfacer las órdenes y la solución de ese problema es usada en una segunda etapa como dato en el problema de scheduling, el cual consiste entonces en determinar la asignación, secuenciamiento y los tiempos de inicio y fin de la operación de los lotes que se

deben procesar. Dicha descomposición del problema se ha realizado, principalmente, a causa de la complejidad del mismo; sin embargo, debido a la estrecha relación existente entre los problemas de batching y scheduling, las soluciones obtenidas resolviendo el problema en dos fases pueden resultar muy inferiores en comparación a las que se obtienen al resolver ambos problemas de manera simultánea. Esta diferencia en las soluciones resulta especialmente notoria en el caso de plantas multiproducto que cuentan con unidades diferentes operando en paralelo y fuera de fase en cada etapa. Prasad y Maravelias [5] han presentado el primer enfoque que considera la optimización simultánea de ambas decisiones, y desde entonces algunos enfoques en esta área, con ciertas limitaciones y características, han sido presentados ([6], [7]). Más recientemente, Fumero y col. [8] han desarrollado un modelo de programación mixta-entera lineal (MILP) basado en slots para optimizar simultáneamente las decisiones de batching y scheduling para una planta batch multiproducto multietapa que opera a través de campañas de producción mixtas. Los trabajos mencionados recientemente, como así también la gran mayoría de modelos propuestos para el problema de scheduling en este tipo de ambientes, adoptan una representación continua del tiempo. Un primer modelo de tiempo discreto que integra las decisiones de batching y scheduling en plantas secuenciales ha sido propuesto por Sundaramoorthy y col. [9], donde los autores enfatizan algunas ventajas de esta representación frente a las de tiempo continuo, presentando flexibilidad para incorporar el modelado de diversas características del proceso tales como tiempos de transición, niveles de inventario, recursos limitados, operaciones de mantenimiento, etc. Más aún, estudios recientes han mostrado que los modelos de tiempo discreto son más efectivos, desde el punto de vista computacional, para problemas de gran escala (Merchan y col. [10]).

Sobre ambientes de producción secuencial, pero más generales, como es el caso de plantas batch multipropósito, Lee y Maravelias [11] han desarrollado modelos de scheduling con representación de tiempo discreto, considerando almacenamiento intermedio finito. Posteriormente, estos autores propusieron formulaciones MILP de tiempo discreto para optimizar simultáneamente las decisiones de batching y scheduling en este contexto, introduciendo un mecanismo de agrupación de unidades en conjuntos que son capaces de procesar cierto rango de tamaños posibles de los batches ([12]).

En este trabajo se desarrolla un novedoso modelo MILP para la resolución simultánea de los problemas de batching y scheduling en una planta secuencial, multiproducto, que cuenta con unidades diferentes operando en paralelo en cada etapa y que no admite almacenamiento intermedio. Se introduce por primera vez el concepto de camino de producción, llamando así a cada una de las posibles trayectorias de un batch a través de una secuencia de unidades en la planta, una de cada etapa. De esta manera, con una única decisión, es posible asignar un batch a todas las unidades en que será procesado para obtener el producto deseado. Esta representación facilita la determinación del tamaño posible del batch sobre ese camino, como así también los cálculos de tiempos. Teniendo en cuenta que sólo se debe determinar el tiempo de procesamiento inicial de cada batch en la unidad correspondiente a la primera etapa, se adopta una representación de tiempo discreto. En general, el problema consiste en determinar el número de batches que se deben procesar para satisfacer la demanda conocida de un conjunto de órdenes, hallar el secuenciamiento de los mismos y los

tiempos iniciales y finales de procesamiento de cada batch de modo que se minimice el makespan, es decir el tiempo total de procesamiento.

2 Descripción del problema

En este trabajo se aborda la solución simultánea de los problemas de batching y scheduling para el caso de una planta de producción batch multiproducto, compuesta por múltiples etapas $j \in J$, donde cada una de ellas cuenta con unidades $k \in KJ_j$ de diferentes tamaños operando en paralelo y fuera de fase.

La planta debe procesar órdenes $d \in D$ por una cantidad Q_d, las cuales pueden ser satisfechas por uno o varios batches de diferentes tamaños. Cada orden monoproducto tiene asociada una fecha de emisión a partir de la cual puede comenzar a procesarse, denotada por RD_d, y otra para la cual debe completarse, denominada DD_d.

El tamaño V_k de cada unidad $k \in KJ_j$, el tiempo de procesamiento t_{dk} de cada batch que se procese para la orden d en la unidad k, el factor de tamaño SF_{dj}, que indica el tamaño requerido en la etapa j para producir una unidad de masa de d como así también el porcentaje mínimo de uso en cada unidad k para procesar un batch de la orden d, indicado con α_{dk}, son parámetros del problema.

Cada batch debe ser procesado siguiendo la misma serie de etapas y no se permite el almacenamiento intermedio. Por lo tanto se adopta la política de transferencia de espera cero (Zero-Wait o ZW), es decir, cada batch que ha sido procesado en una etapa debe ser transferido inmediatamente a la siguiente. El tiempo requerido para realizar dicha transferencia se considera despreciable.

El problema consiste en determinar el número de batches que se deben procesar para satisfacer la demanda de cada orden, las unidades en que se procesa cada batch y realizar el secuenciamiento de los batches calculando el tiempo inicial y final de procesamiento de cada uno de ellos en cada una de las unidades, teniendo como objetivo minimizar el tiempo total requerido para procesar completamente todas las órdenes, es decir, minimizar el makespan.

3 Formulación del modelo

En este trabajo se considera una planta batch secuencial, donde cada batch debe seguir la misma secuencia a través de todas las etapas de la planta y ser procesado en exactamente una unidad de cada etapa. Cada batch se trata de manera individual durante el procesamiento, es decir, no se divide ni se mezcla con otros batches. A partir de las condiciones anteriores surge la propuesta de que durante su procesamiento cada batch sigue un camino pasando por una unidad en cada etapa. Formalmente se define un camino de producción $r \in R$ como una $|J|-upla$ de la forma $(k_1, k_2, \ldots, k_{|J|})$ donde $k_1 \in KJ_1, k_2 \in KJ_2, \ldots, k_{|J|} \in KJ_{|J|}$. Por lo tanto, el número total de caminos posible resulta $|R| = \prod_{j=1}^{j=|J|} |KJ_j|$.

El concepto de camino, que se introduce por primera vez en este trabajo, permite una simplificación importante en la formulación del modelo, ya que al asignar un batch a un camino se está realizando la asignación simultánea del mismo a todas las unidades donde se procesará, a diferencia de las formulaciones previas que asignan los batches a cada unidad de manera individual.

Puesto que son conocidos el volumen de cada unidad, su porcentaje mínimo de ocupación y el factor de tamaño de cada orden en las diferentes etapas, es posible determinar los tamaños mínimo y máximo factibles en cada camino para un batch de cada orden, lo cual permite plantear restricciones para satisfacer la demanda sin tener que determinar explícitamente el tamaño de cada batch.

Por último, pero no menos importante, dado que la planta opera con política de transferencia zero-wait (ZW), basta con conocer el tiempo en el cual se comienza a procesar cada batch en el camino al que se asignó para que queden completamente determinados los tiempos en que el batch se procesará en cada unidad del camino y el tiempo final de procesamiento. Esto permite adoptar una representación de tiempos discretos donde se propone una grilla con los posibles tiempos de inicio de procesamiento en cada camino, evitando de esta manera introducir variables para la determinación del tiempo de inicio de procesamiento en cada unidad.

3.1. Cotas para el número de batches

Se define el conjunto KR_r que contiene las unidades que conforman el camino r. Entonces, los tamaños mínimo y máximo que admite el camino r para un batch de la orden d están dados, respectivamente, por las siguientes expresiones:

$$B_{dr}^{\min} = \max_{j \in J} \left\{ B_{drj}^{\min} \right\} \qquad \forall d \in D, r \in R$$

$$B_{dr}^{\max} = \min_{j \in J} \left\{ B_{drj}^{\max} \right\} \qquad \forall d \in D, r \in R$$

donde

$$B_{drj}^{\min} = \alpha_{dk} \frac{V_k}{SF_{dj}} \qquad \forall d \in D, r \in R, j \in J, k \in KR_r, k \in KJ_j$$

$$B_{drj}^{\max} = \frac{V_k}{SF_{dj}} \qquad \forall d \in D, r \in R, j \in J, k \in KR_r, k \in KJ_j$$

Notar que los parámetros B_{drj}^{min} y B_{drj}^{max} están bien definidos ya que para cada etapa j, existe una única unidad k asociada al camino r.

Debido a que las unidades de la planta son de diferentes tamaños, tienen porcentaje mínimo de ocupación y se consideran distintos factores de tamaño para cada orden, puede ocurrir que el tamaño máximo admisible en una unidad sea menor que el tamaño mínimo determinado para otra unidad del mismo camino. Obviamente, no es posible procesar un batch de esa orden en ese camino. En ese caso, resulta que

$B_{dr}^{\min} > B_{dr}^{\max}$. Por lo tanto, se define para cada orden d el conjunto FAC_d de todos los caminos r en los cuales es posible procesar un batch de esa orden, es decir, en los que cuales $B_{dr}^{\min} \le B_{dr}^{\max}$.

A partir de los tamaños factibles para los batches de las diferentes órdenes en cada camino, resulta que los tamaños mínimo y máximo admisibles para cada batch de la orden d en la planta están dados por:

$$B_d^{\min} = \min_{r \in FAC_d} \left\{ B_{dr}^{\min} \right\} \qquad \forall d \in D$$

$$B_d^{\max} = \max_{r \in FAC_d} \left\{ B_{dr}^{\max} \right\} \qquad \forall d \in D$$

Luego, los números mínimo y máximo de batches en que puede ser dividida cada orden son, respectivamente:

$$NB_d^{\min} = \left\lceil \frac{Q_d}{B_d^{\max}} \right\rceil \qquad \forall d \in D$$

$$NB_d^{\max} = \left\lfloor \frac{Q_d}{B_d^{\min}} \right\rfloor \qquad \forall d \in D$$

donde se han usado las funciones piso y techo para obtener el número entero.

El número de batches que se procesarán para satisfacer la orden d es una variable del problema, por lo que se propone el conjunto N_d de números enteros positivos comprendidos entre $NB_d^{\min}$ y $NB_d^{\max}$, de los cuales sólo uno será seleccionado. Para representar esta selección, se introduce la siguiente variable binaria:

$$x_{dn} = \begin{cases} 1 & \text{si la orden } d \text{ es dividida en } n \text{ batches} \\ 0 & \text{en otro caso} \end{cases}$$

la cual debe satisfacer la ecuación

$$\sum_{n \in N_d} x_{dn} = 1 \quad \forall d \in D \tag{1}$$

3.2. Asignación de los batches a los caminos

Los diferentes batches b que se utilizarán para satisfacer la orden d, se identifican, según el número requerido n de ellos, de la siguiente manera: si la orden d se procesa en un único batch (n = 1), éste se indica como *b1*; si se divide en dos batches (n = 2), se denominan *b1* y *b2*; y así sucesivamente. Para formalizar lo anterior, para cada orden d y número de batches n que se utilicen para su procesamiento, se introduce el conjunto DB_{dn}={*b1,b2,...bn*}.

Cada batch b requerido para completar la orden d se asigna a un único camino r, a través de la variable

$$z_{dnbr} = \begin{cases} 1 & \text{si la orden } d \text{ es dividida en } n \text{ batches y el batch } b \text{ es} \\ & \text{asignado al camino } r \\ 0 & \text{en otro caso} \end{cases}$$

Teniendo en cuenta los tamaños admisibles en cada camino, el tamaño de la orden y el número de batches en que ésta se puede dividir para ser procesada, no todas las combinaciones de asignación batch-camino resultarán factibles. El objetivo es construir para cada orden d, número de batches n en que se divide y batch b que se procesa, el conjunto POS_{dnb} que contenga sólo los caminos r a los que efectivamente es posible asignar el batch b.

Antes de plantear el caso general se introduce un ejemplo sencillo pero esclarecedor: se considera una planta que cuenta con tres caminos *r1*, *r2* y *r3* en los cuales se pueden procesar batches cuyo tamaño (en kg) se encuentra entre 140 y 210, 80 y 120, 60 y 90, respectivamente. Se debe procesar una orden de 190 kg. Las posibles soluciones son:

a) procesar un único batch *b1* en el camino r1 ($n = 1$).

b) la orden se divide en dos batches *b1* y *b2* ($n = 2$). Acá es posible realizar la asignación de dos maneras: ambos batches a *r2* (ya que $80+80 \leq 190 \leq 120+120$), o bien un batch a *r2* y el otro a *r3* ($60+80 \leq 190 \leq 90+120$). Todas las demás asignaciones con dos batches resultan no factibles. Cabe remarcar que en el segundo caso es posible asignar *b1* a *r2* y *b2* a *r3* o viceversa. Dado que ambas soluciones son equivalentes, se adopta realizar la asignación en forma creciente, es decir, el batch con una etiqueta menor se asigna al camino menor, en este caso *b1* a *r2* y *b2* a *r3*.

c) la orden se divide en tres batches *b1*, *b2* y *b3* ($n = 3$); en este caso los tres batches deben ser asignados al camino *r3* ($3*60 \leq 190 \leq 3*90$), todas las demás asignaciones resultan no factibles.

Por lo tanto, en este caso los conjuntos POS_{dnb} antes descriptos resultan:

a) en caso de hacer un solo batch $POS_{d,1,b1} = \{r1\}$;

b) si se hacen dos batches $POS_{d,2,b1} = \{r2\}$, $POS_{d,2,b2} = \{r2,r3\}$;

c) por último si se hacen tres batches $POS_{d,3,b1} = POS_{d,3,b2} = POS_{d,3,b3} = \{r3\}$.

Planteando el caso general, resulta que únicamente es posible procesar la orden d dividida en n batches $b1, b2, \ldots, bn \in DB_{dn}$ asignados a los caminos $r_{m1}, r_{m2}, \ldots, r_{mn} \in FAC_d$ (los cuales pueden estar repetidos) si se cumple que $\sum_{h=1}^{n} B_{dr_{mh}}^{\min} \leq Q_d \leq \sum_{h=1}^{n} B_{dr_{mh}}^{\max}$. Dentro de cada una de estas asignaciones factibles se selecciona la que realiza la asignación batch-camino en forma creciente, descartando las soluciones equivalentes, como se ha detallado en el ejemplo. A partir de todas las asignaciones batch-camino que satisfagan las condiciones anteriores se crean los conjuntos POS_{dnb} cuyos elementos son los caminos r a los que efectivamente es posible asignar el batch b si la orden d se divide en n batches para ser procesada. La introducción de dichos conjuntos reduce notablemente la combinatoria del problema de asignación batch-camino, especialmente cuando los tamaños admisibles en los caminos de la planta difieren entre sí. Además este preprocesamiento se puede realizar antes de resolver el problema a partir de los datos disponibles.

La siguiente ecuación asegura que cada batch que se utilice para satisfacer una orden sea asignado a un único camino para su procesamiento:

$$\sum_{r \in POS_{dnb}} z_{dnbr} = x_{dn} \qquad \forall d \in D, n \in N_d, b \in DB_{dn} \tag{2}$$

Con el fin de evitar soluciones redundantes, la asignación batch-camino se realiza en forma creciente, es decir si los batches $b, b' \in DB_{dn}$ con $b' < b$ son asignados a los caminos $r, r' \in FAC_d$ donde $r' < r$, entonces b se asigna a r y b' a r'

$$\sum_{\substack{r' \in POS_{dnb+1} \\ r' < r}} z_{dnb+1r'} \leq 1 - z_{dnbr} \qquad \forall d \in D, n \in N_d, n \geq 2, b, b+1 \in DB_{dn}, r \in POS_{dnb} \tag{3}$$

3.3. Restricciones de tiempo y secuenciamiento

En este modelo se utiliza una representación de tiempo discreto, en la cual se propone una grilla equiespaciada de puntos $t \in T$ teniendo en cuenta las fechas de emisión y entrega de las órdenes. Para simplificar la representación se supone que el menor de los tiempos de inicio es igual a 0 y los demás tiempos de inicio y fechas de entrega se proponen respecto a dicho tiempo inicial. El paso Δt de la grilla es igual al máximo común divisor entre los tiempos de procesamiento de todas las órdenes en cada una de las unidades.

Si se procesa un batch de la orden d en el camino r el tiempo total de procesamiento del mismo es

$$t_{dr} = \sum_{k \in KR_r} t_{dk} \qquad \forall d \in D, r \in FAC_d$$

con lo cual sus posibles tiempos de inicio $t \in TDR_{dr}$ son aquellos que satisfacen: $RD_d \leq t \leq DD_d - t_{dr}$.

Se introduce la variable binaria y_{dnbrt}:

$$y_{dnbrt} = \begin{cases} 1 & \text{si la orden } d \text{ es dividida en } n \text{ batches y el batch } b \text{ se comienza} \\ & \text{a procesar en el camino } r \text{ en el punto de tiempo } t \\ 0 & \text{en otro caso} \end{cases}$$

Se debe asignar cada batch procesado a un único tiempo de inicio, lo cual se impone a través de la siguiente ecuación

$$\sum_{t \in TDR_{dr}} y_{dnbrt} = z_{dnbr} \qquad \forall d \in D, n \in N_d, b \in DB_{dn}, r \in POS_{dnb} \tag{4}$$

El secuenciamiento de batches se realiza de manera implícita imponiendo que en cada unidad y en cada punto de la grilla de tiempos se puede procesar como máximo un batch. Además, esto evita el solapamiento en los procesamientos de batches en

cada unidad de la planta. El modelo determina únicamente el tiempo inicial de operación de cada batch en la primera unidad del camino donde se procesa. Por lo tanto, para determinar en qué puntos de tiempo se procesa en las unidades del camino que no pertenezcan a la primera etapa, deben tenerse en cuenta el tiempo de inicio y los tiempos de procesamiento en las unidades previas del camino.

Sea d una orden y $r \in FAC_d$, $r = (k_1, k_2, ..., k_j, ... k_{|J|})$ con $k_1 \in KJ_1$, $k_2 \in KJ_2$, … $k_j \in KJ_j$,… $k_{|J|} \in KJ_{|J|}$, un camino de producción en el cual es posible procesar un batch de la orden d. Para cada unidad k que compone el camino r, se definen los parámetros TL_{drk} y TU_{drk}, que corresponden a los tiempos totales de procesamiento de cualquier batch de la orden d hasta la unidad k y hasta la unidad anterior a ésta en el camino, respectivamente:

$$TL_{drk} = \sum_{j'=1}^{j} \sum_{\substack{k' \in KJ_{j'} \\ k' \in KR_r}} t_{dk'} \qquad \forall d \in D, j \in J, k \in KJ_j, r \in FAC_d, r \in RK_k$$

$$TU_{drk} = \sum_{j'=1}^{j-1} \sum_{\substack{k' \in KJ_{j'} \\ k' \in KR_r}} t_{dk'} \qquad \forall d \in D, j \in J, j \geq 2, k \in KJ_j, r \in FAC_d, r \in RK_k$$

con $TU_{drk} = 0 \; \forall \; d \in D, j = 1, k \in KJ_1, r \in FAC_d, r \in RK_k$, siendo RK_k el conjunto de caminos que pasan por la unidad k.

Sea t un punto genérico de la grilla de tiempos propuestos y k_j la unidad sobre la etapa j que corresponde al camino r. Para determinar si un batch de la orden d inicia su procesamiento o se esté procesando en el tiempo t en la unidad k_j, se deben calcular los posibles tiempos de inicio de operación para el batch en la unidad k_1 correspondiente a la primera etapa de la planta. Como se puede observar desde la Figura 1, el tiempo más tardío de inicio en la unidad k_1 para que el batch de la orden d inicie su procesamiento en el tiempo t en la unidad k_j se calcula como $t - TU_{drk_j}$, mientras que el tiempo más temprano de inicio en la unidad k_1 para que el batch se esté procesando en el tiempo t en k_j es $t - TL_{drk_j} + 1$. En consecuencia, resulta que un batch de la orden d asignada al camino r se esta procesando en el tiempo t en la unidad k_j, si y sólo si uno de los puntos del intervalo $[t - TL_{drk_j} + 1, t - TU_{drk_j}]$, los cuales están representados en la Figura 1 con círculos azules, es seleccionado para su inicio.

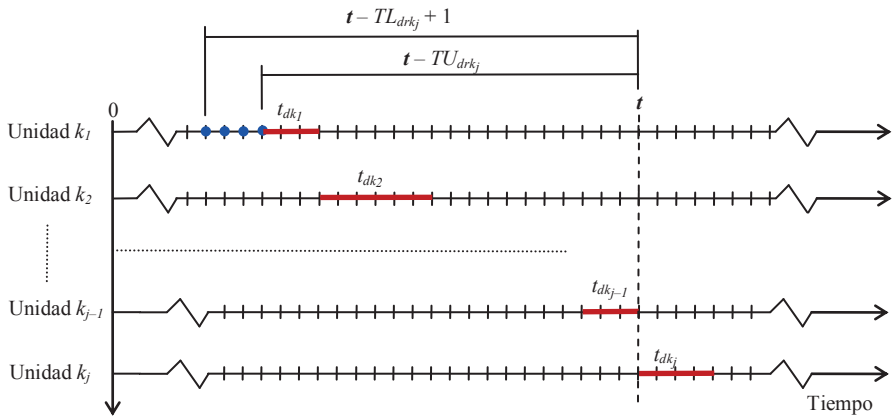

Fig. 1. Grillas de tiempos para el secuenciamiento en la unidad k_j de la etapa j

En general, un batch de la orden d asignada al camino r se estará procesando en el punto t de la grilla sobre la unidad k que forma parte del camino r si y sólo si su procesamiento se inicia en algún punto de tiempo t' con $t - TL_{drk} + 1 \leq t' \leq t - TU_{drk}$.

De esta manera, considerando todas las órdenes, batches posibles en los que se pueda particionar y caminos factibles para sus procesamientos, se puede asegurar que en el punto de tiempo t y en la unidad k no se estará procesando más de un batch si se satisface la siguiente restricción:

$$\sum_{d\in D}\sum_{n\in N_d}\sum_{b\in DB_{dn}}\sum_{\substack{r\in POS_{dnb}\\ r\in RK_k}}\sum_{t'=t-TL_{drk}+1}^{t-TU_{drk}} y_{dnbrt'} \leq 1 \qquad \forall j \in J, k \in KJ_j, t \in T \tag{5}$$

Con el fin de romper la simetría del problema y evitar soluciones redundantes se impone que si dos batches b, b' de la orden d, con $b < b'$, son asignados al mismo camino r entonces el tiempo de inicio de procesamiento de b es menor al de b', esto es

$$\sum_{\substack{t'\in TDR_{dr}\\ t'<t+t_{dk}}} y_{dnb+1rt'} = 1 - y_{dnbrt} \qquad \forall d \in D, n \in N_d, n \geq 2, b, b+1 \in DB_{dn}, \quad t \in TDR_{dr}, k \in KJ_1, r \in POS_{dnb}, r \in RK_k \tag{6}$$

3.4. Satisfacción de la demanda

Debe ser factible satisfacer la demanda de cada orden con el número de batches en que se divide y los caminos a los cuales se asignan, para que esto ocurra, debe satisfacerse la desigualdad

$$\sum_{n\in N_d}\sum_{b\in DB_{dn}}\sum_{r\in POS_{dnb}}\sum_{t\in TDR_{dr}} B_{dr}^{\min} y_{dnbrt} \leq Q_d \leq \sum_{n\in N_d}\sum_{b\in DB_{dn}}\sum_{r\in POS_{dnb}}\sum_{t\in TDR_{dr}} B_{dr}^{\max} y_{dnbrt} \qquad \forall d \in D \tag{7}$$

3.5. Función objetivo

El objetivo es minimizar el makespan (*MK*), es decir el máximo tiempo requerido para procesar todas las órdenes. La siguiente ecuación asegura que *MK* sea mayor o igual que cada uno de los tiempos finales de procesamiento

$$MK \geq (t + t_{dr})y_{dnbrt} \qquad \forall d \in D, n \in N_d, b \in DB_{dn}, r \in POS_{dnb}, t \in TDR_{dr} \tag{8}$$

luego, el modelo resulta

$$\text{Minimizar } MK \tag{9}$$

sujeto a las restricciones 1 a 8.

4 Ejemplo

En esta sección se presenta un ejemplo que permite mostrar tanto la capacidad para generar una solución para el problema como la performance computacional del modelo desarrollado en este trabajo. Se considera una planta batch de tres etapas, con dos unidades diferentes en cada una de ellas, operando en paralelo y fuera de fase. La estructura, como así también las capacidades máximas de las unidades, son conocidas, y se ilustran en la Figura 2.

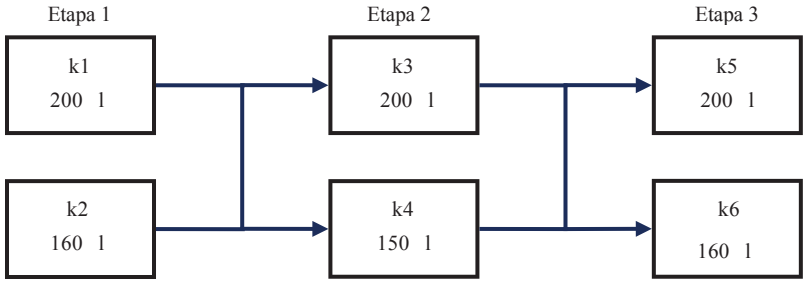

Fig. 2. Estructura de la planta

De acuerdo a la estructura de la planta, es posible definir 8 caminos diferentes. Para simplificar, en este ejemplo, se consideran los factores de tamaño iguales a uno para todas las órdenes y todas las etapas, mientras que el porcentaje mínimo de ocupación es del 70% en cada unidad. Teniendo en cuenta estas consideraciones, es posible determinar los tamaños mínimos y máximos admisibles para cada batch en cada camino, independientemente de la orden. Las unidades que componen cada camino como así también los tamaños mínimo y máximo en cada uno de ellos se muestran en la Tabla 1.

Tabla 1. Definición de los caminos y tamaños admisibles para los batches

Camino	Unidad de cada etapa que compone el camino			$B_r^{\min}$	$B_r^{\max}$
	Etapa 1	Etapa 2	Etapa 3		
r1	k1	k3	k5	140	200
r2	k1	k3	k6	140	160
r3	k1	k4	k5	140	150
r4	k1	k4	k6	140	150
r5	k2	k3	k5	140	160
r6	k2	k3	k6	140	160
r7	k2	k4	k5	140	150
r8	k2	k4	k6	112	150

La planta debe procesar un conjunto de doce órdenes {d1, d2,…, d12}, cuyas demandas, fechas de emisión y límite de entrega, y tiempos de procesamiento se presentan en la Tabla 2.

Tabla 2. Demandas, fecha de emisión y vencimiento y tiempos de procesamiento de las órdenes

Orden	Q_d (kg)	RD_d	DD_d	Tiempos de procesamiento t_{dk} (hs)					
				k1	k2	k3	k4	k5	k6
d1	380	0	30	3	4	3	4	4	5
d2	130	0	25	4	4	3	3	4	4
d3	225	0	25	5	4	5	4	6	5
d4	190	5	25	2	3	2	2	3	4
d5	340	5	40	3	3	3	4	3	4
d6	530	0	35	2	2	3	3	2	3
d7	430	0	35	5	4	5	4	5	4
d8	390	10	45	2	3	2	3	3	4
d9	300	10	50	4	3	3	5	5	4
d10	340	10	50	2	2	2	3	3	3
d11	290	15	45	5	4	5	4	5	4
d12	360	15	50	2	3	2	2	3	4

Tabla 3. Batching y scheduling óptimo de las órdenes

Orden	Batches	Camino	Tiempo de inicio (hs)	Tiempo final (hs)
d1	b1	r1	2	12
	b2	r1	6	16
d2	b1	r8	0	11
d3	b1	r8	4	17
	b2	r8	9	22
d4	b1	r1	18	25
d5	b1	r1	10	19
	b2	r5	13	22
d6	b1	r1	0	7
	b2	r1	23	30

	b3	r1	28	35
d7	b1	r4	13	26
	b2	r8	18	30
	b3	r8	22	34
d8	b1	r1	21	28
	b2	r1	31	38
d9	b1	r2	34	45
	b2	r8	37	49
d10	b1	r1	26	33
	b2	r6	34	41
d11	b1	r7	30	43
	b2	r8	26	38
d12	b1	r1	39	46
	b2	r1	42	49

Para la resolución del problema se propone una grilla de tiempos discretos desde 0 hasta 50 o sea, desde 0 hasta la mayor de las fechas de vencimiento, con paso $\Delta t = 1$ que es el máximo común divisor entre todos los tiempos de procesamiento.

El ejemplo fue implementado en GAMS versión 24.7.4 y resuelto empleando el solver CPLEX 12.6.3, con un procesador Intel Core i7, 2.7 GHz, 12 GB de RAM. El modelo consta de 5410 ecuaciones, 7308 variables discretas y 1 variable continua correspondiente al makespan. La obtención del óptimo global demandó un tiempo de CPU de 52 segundos.

En la solución óptima el makespan resulta ser 49 horas. En la Tabla 3 se resumen los resultados obtenidos, indicando los batches en que se divide cada orden, los caminos en que se procesa cada batch y los tiempos iniciales y finales de procesamiento de los mismos, a fin de satisfacer los requerimientos de demanda en el mínimo tiempo total de procesamiento. Como puede observarse, es necesario procesar 24 batches para satisfacer la demanda de las 12 órdenes. Las órdenes d6 y d7 debieron ser divididas en tres batches cada una, d2 y d4 pudieron ser completadas con un único batch, mientras que las restantes han sido satisfechas empleando dos batches. Cada orden satisface su fecha de emisión y límite de entrega.

En la Figura 3, se ilustra el diagrama de Gantt de la solución óptima.

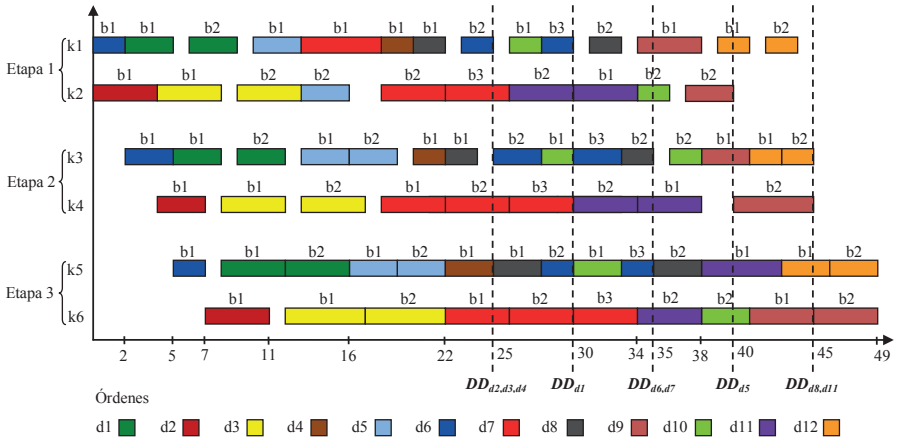

Fig. 3. Diagrama de Gantt de la solución óptima

5 Conclusiones

El modelo desarrollado en este trabajo permite resolver simultáneamente los problemas de batching y scheduling minimizando el tiempo total de procesamiento, proporcionando el número de batches en que se divide cada orden, las unidades en que se procesa cada batch y sus tiempos inicial y final de procesamiento. La nueva representación para decidir el procesamiento de las órdenes, basada en caminos de producción, y la definición de tiempos discretos, han demostrado ser computacionalmente eficiente, permitiendo resolver problemas de considerable tamaño en tiempos reducidos. De este modo, se proporciona una herramienta eficiente para optimizar la operación de una planta batch multiproducto.

Abstract. La necesidad de generar programas de producción sustentables, ha contribuido a nuevos desarrollos innovadores en la gestión de operaciones. En muchos casos se han generado enfoques y herramientas que permitieron mejorar la sustentabilidad de las industrias. Dentro de esas mejoras, un tema recurrente, es la reducción del consumo energético y de las emisiones de carbono. En este trabajo se aborda el problema de scheduling de flow-shop con consideraciones energéticas utilizando estrategias de lot-streaming. Las estrategias de lot-streaming permiten dividir un trabajo (o lote de un mismo producto) en pequeños sublotes, de forma que esos sublotes puedan avanzar de etapa de producción, aun cuando parte del trabajo sigue procesándose en la etapa de producción anterior. El consumo energético se modela dentro de la función objetivo, junto con el makespan, por medio de una suma normalizada y ponderada. De esta forma, la reducción del consumo energético guía el proceso de optimización. Los experimentos evalúan el impacto de utilizar estrategias de lot-streaming en este tipo de problemas. Los resultados permitieron demostrar que el lot-streaming es una estrategia eficiente a la hora de resolver este problema, permitiendo mejorar tanto el makespan como el consumo energético total con respecto al problema sin lot-streaming. A su vez, se incorporó la selección de velocidades de procesamiento para cada sublote, lo que mejoró la estrategia.

Keywords: Scheduling, flow-shop, lot-streaming, operaciones sustentables.

1 Introducción

En las últimas décadas ha crecido la conciencia global sobre la necesidad de cambiar a sistemas industriales más sustentables [1]. Esto disminuiría los impactos negativos del

cambio climático reduciendo las emisiones de carbono [2]. Una de las formas más directa de reducir estas emisiones es disminuir el consumo energético, reduciendo así, la combustión de combustibles fósiles [3]. Dentro de la producción de productos manufacturados, la reducción del consumo energético puede abordarse desde tres perspectivas distintas [4] [5]:

1. A nivel de la maquinaria: se busca desarrollar máquinas más eficientes y que requieran menos cantidad de energía.

2. A nivel del producto: se busca diseñar un producto desde el punto de vista del ahorro energético. Esto no es muy factible en empresas medianas y pequeñas ya que requiere mucha inversión.

3. A nivel de la fábrica: se puede optar por un modelo de decisiones que soporten y contribuyan al ahorro energético.

Este trabajo se enmarca en esta última perspectiva, buscando desarrollar herramientas de apoyo a la toma de decisión que contribuyan al ahorro energético, puntualmente considerando problemas de scheduling. Incluir consideraciones energéticas en la resolución de problemas de scheduling mostró ser muy efectiva en la reducción energética, logrando reducciones de hasta el 80% [6]. Dentro de los primeros trabajos sobre esta línea resalta el trabajo de Mouzon et al. [3], en donde los autores desarrollaron un estudio de reglas de despacho, y luego un modelo multi-objetivo que permitió resolver el scheduling reduciendo considerablemente los consumos energéticos para máquinas del tipo CNC (Control Numérico de Computadoras). Un aspecto crítico a la hora de buscar reducir el consumo energético, es minimizar la potencia máxima consumida por el proceso productivo, ya que cuando se incrementa la potencia el consumo energético aumenta más que proporcionalmente (es decir, la proporcionalidad entre aumento de potencia entregada en el eje de la máquina y el aumento en el consumo energético es exponencial). Por lo que, buscar minimizar el pico máximo de consumo energético contribuye a la eficiencia energética, y en consecuencia a minimizar las emisiones de carbono [7]. Este enfoque de buscar minimizar el pico de consumo energético fue abordado por primera vez por Fang et al. [8]. En ese trabajo los autores desarrollaron modelos matemáticos multi-objetivos que buscaron minimizar el pico de consumo en un sistema flow-shop, el makespan y las emisiones de carbono. Esos modelos consideraron la velocidad de procesamiento de cada operación como una variable de decisión. Mientras que Fang et al. [9] profundizaron su estudio al considerar nuevamente sistemas flow-shop buscando minimizar el consumo energético, pero desarrollan formulaciones matemáticas fortalecidas, así como enfoques combinatorios que permitieron resolver el problema. A su vez, en ese trabajo, consideraron dos variantes de flow-shop, una sin almacenamiento intermedio entre etapas sucesivas (si no hay almacenamiento intermedio, una máquina no puede liberarse hasta que se libere la siguiente máquina), y otra variante con almacenamiento intermedio ilimitado. Bruzzone et al. [7] abordaron el problema de minimizar el pico de consumo energético, pero en sistemas flow-shop flexibles (más de una máquina en paralelo por etapa). En este trabajo, los autores, plantearon un enfoque de resolución basado en etapas, en donde primero resuelven el scheduling buscando minimizar una función objetivo tradicional como el makespan. Luego,

en una segunda etapa, reprogramar el inicio de las actividades. Por otro lado, Mansouri et al. [10] utilizaron un enfoque multi-objetivo para resolver un sistema flow-shop de 2 etapas. Los objetivos que consideraron los autores fueron el makespan y el consumo energético total, y resolvieron el problema utilizando el método de ε-restricciones.

Sin embargo, hasta donde se conoce, no se han utilizado estrategias de lot-streaming para el problema del flow-shop con consideraciones energéticas. Es por eso que en este trabajo se propone resolver el problema de flow-shop con consideraciones energéticas mediante estrategias de lot-streaming. El lot-streaming permite dividir los lotes de producción en sublotes, los cuales pueden avanzar de una estación de trabajo a otra sin esperar a que se procese el lote completo [11]. De esta forma se puede solapar la producción de un mismo lote en más de una etapa de producción, favoreciendo la eficiencia del sistema al reducir los tiempos de ciclos de producción [12]. Por otro lado, permite reducir los tiempos de makespan considerablemente para sistemas de flow-shop no-permutativos [13], así como lidiar de forma eficiente con sistemas complejos de flow-shop en donde una de las etapas de producción funciona en modo batch [14]. Este trabajo busca implementar el lot-streaming para resolver el scheduling en sistemas flow-shop con consideraciones energéticas. La intención es aprovechar la capacidad de flexibilizar los tiempos de procesamiento de cada lote de producción al poder subdividirlo, y de esta forma flexibilizar el scheduling para minimizar el consumo energético.

2 El problema y los modelos matemáticos

Dada la importancia de considerar el consumo energético dentro de los problemas de scheduling, en este apartado se propone formalmente la incorporación de procesos de lot-streaming al cálculo del schedule. Para ello se parte describiendo detalladamente el problema a estudiar, para luego presentar los modelos matemáticos.

2.1 Problema estudiado

El problema estudiado en este trabajo se enmarca dentro de la línea de scheduling con consideraciones energéticas [3]. En estos problemas se busca resolver el problema clásico de scheduling [15]: asignar los trabajos o tareas a los recursos disponibles buscando minimizar alguna función objetivo. Al incorporar las consideraciones energéticas, se busca minimizar el impacto ambiental que generan las operaciones de producción por dos vías, o minimizar el consumo energético total [6] o el pico máximo de consumo energético [8]. Este trabajo busca minimizar el consumo energético total. Esto tiene razón de ser en entornos en que la velocidad de procesamiento de las tareas es variable, y ligada a esa variabilidad de velocidad está el consumo energético [10]. Por lo tanto, las operaciones aquí consideradas no son tareas constantes, sino que pueden incorporarse como variables de decisión al problema, lo que permite aumentar la eficiencia del schedule obtenido (hay mayores grados de libertad), pero a su vez implica un incremento en la complejidad del mismo [4] [9].

Por otro lado, se propone la innovación de incluir estrategias de lot-streaming al problema. El lot-streaming consiste en la subdivisión de los lotes de producción en

sublotes, de forma que estos puedan avanzar de operación aun cuando el lote completo no ha terminado su procesamiento en la operación anterior [16]. De esta forma, es posible que dos máquinas sucesivas del flow-shop estén procesando el mismo trabajo o lote (dividido en sublotes) simultáneamente [11]. Incorporar lot-streaming al problema considerado en este trabajo permite aumentar la flexibilidad en el proceso de asignación de trabajos, logrando aprovechar las mejoras que reporta lot-streaming a la hora de estudiar el makespan dejando mayor margen para la minimización del consumo energético total.

2.2 Modelos matemáticos

En esta sección se presentan los tres modelos matemáticos estudiados. El primero es el caso más general, flow-shop con consideraciones energéticas (FSS+EA), luego se incorpora la primera aproximación de lot-streaming a ese problema (SBS+EA). Finalmente, se incorpora el lot-streaming a la consideración energética al permitir modificar la velocidad de procesamiento para cada sublote (SBSI+EA).

2.2.1 Flow-shop con consideraciones energéticas (FSS+EA)

El primer modelo presentado se trata del problema clásico de scheduling en flow-shop con consideraciones energéticas (FSS+EA). Este modelo busca secuenciar los trabajos cumpliendo con las condiciones de producción (es decir que se respeten todas las operaciones que deben realizarse en cada trabajo), pero también, definiendo la velocidad de procesamiento de cada operación. Por lo que, tanto el secuenciamiento como la selección de velocidades de procesamiento intervienen en el cálculo de la función objetivo que contempla el makespan y el consumo energético. Estos objetivos son abordados a través de una suma ponderada normalizada. Además, como característica realista del problema, se contemplaron tiempos de preparación y remoción para cada trabajo. El modelo matemático se presenta a continuación.

Índices:

M: máquinas; $k = 1, 2, \ldots, m$.

J: trabajos o lotes; $j = 1, 2, \ldots, n$.

V: velocidad de procesamiento; $l = 1, 2, 3$.

Parámetros:

G: valor positivo lo suficientemente grande.

m: número de máquinas.

n: número de trabajos o lotes.

U_j: cantidad de unidades de producto j a procesar (tamaño del lote de producto j).

$TS_{j,k}$: tiempo de setup del trabajo j en la máquina k.

$P_{j,k}$: carga de trabajo estándar de procesar una unidad de producto j en la máquina k [segundos].

$RT_{j,k}$: tiempo de liberar la máquina k luego de procesar una unidad o más del producto j (es independiente de la cantidad de unidades procesadas).

$Vl1_l$: factor de velocidad para la velocidad seleccionada l. Puede tomar los valores 1.2, 1 y 0.8.

$Vl2_l$: factor de conversión energética para la velocidad de procesamiento l. Toma los valores 1.5, 1, 0.6 para rápido, normal y lento, respectivamente.

MO_k: factor de conversión energético para el tiempo ocioso de la máquina k.

PM_k: potencia de la máquina k.

Variables:

$C_{j,k}$: tiempo en completar el trabajo j en la máquina k.

$X_{j,jj}$: variable binaria, es 1 si el trabajo j se procesa antes que el trabajo jj, 0 en otro caso ($j \neq jj$).

$Y_{j,k,l}$: variable binaria, es 1 si el trabajo j se procesa a la velocidad l en la máquina k, 0 en otro caso.

C_{max}: tiempo de completar el último trabajo o makespan. (Nota: C_{max}^{min} representa el valor mínimo posible de C_{max} para esa instancia, C_{max}^{max} representa el valor máximo posible de C_{max} para esa instancia, C'_{max} representa el valor actual de la solución obtenida)

TEC: consumo energético. (Nota: TEC^{min} representa el valor mínimo posible de TEC para esa instancia, TEC^{max} representa el valor máximo posible de TEC para esa instancia, TEC' representa el valor actual de la solución obtenida)

Formulación:

$$\text{Minimizar } Z = 0.5 * \left(\frac{C'_{max} - C_{max}^{min}}{C_{max}^{max} - C_{max}^{min}}\right) + 0.5 * \left(\frac{TEC' - TEC^{min}}{TEC^{max} - TEC^{min}}\right) \quad (1)$$

Desglose de Z (ecuación 1):

$$C'_{max} \geq C_{j,k} + RT_{j,k}, \forall j, k = m \quad (2)$$

$$TO_k = C_{max} - \sum_j \sum_l \frac{P_{j,k} * U_j}{Vl1_l} * Y_{j,k,l}, \forall\, k \quad (3)$$

$$TEC' = \sum_k \sum_j \sum_l \frac{PM_k * P_{j,k} * U_j * Vl2_l}{60 * Vl1_l} * Y_{j,k,l} + \sum_k \frac{MO_k * PM_k}{60} * TO_k \quad (4)$$

Sujeto a:

$$C_{j,k} \geq \frac{P_{j,k} * U_j}{Vl1_l} * Y_{j,k,l} + TS_{j,k}, \forall j, k = 1 \quad (5)$$

$$C_{j,k} \geq C_{j,k-1} + \frac{P_{j,k} * U_j}{Vl1_l} * Y_{j,k,l} + RT_{j,k-1} + TS_{j,k}, k > 1, \forall j \quad (6)$$

$$C_{jj,k} \geq C_{j,k} + \frac{P_{jj,k} * U_{jj}}{Vl1_l} * Y_{jj,l,k} - G * \left(1 - X_{j,jj}\right) + RT_{j,k} + TS_{jj,k}, \forall k, jj \neq j \quad (7)$$

$$X_{j,jj} + X_{jj,j} = 1, jj \neq j \quad (8)$$

$$\sum_l Y_{j,k,l} = 1, \forall\, j, k \quad (9)$$

La función objetivo *Z* se presenta en la ecuación (1), en donde se muestra que la misma se compone por el makespan (C_{max}) y el consumo energético (*TEC*). También, en la ecuación (1), se muestra cómo es la normalización de *Z* para cada uno de los términos, y también las ponderaciones consideradas para este trabajo de 0.5. El cálculo de C_{max} se realiza según la ecuación (2). En la ecuación (3) se calcula el tiempo ocioso TO_k. Y en la ecuación (4) se obtiene el consumo energético, considerando las velocidades seleccionadas para procesar cada trabajo, así como el consumo durante el tiempo ocioso afectado por un factor de 60 segundos. Luego, se presentan las restricciones en las ecuaciones (5) - (9). La restricción (5) secuencia los trabajos para la primera máquina. En la restricción (6) se asegura que cada trabajo respete sus condiciones de precedencia entre operaciones. La restricción (7) secuencia los distintos trabajos, si el trabajo *j* se procesa antes que el trabajo *jj* para la máquina *k*, entonces se mantiene ese orden para todas las máquinas. La restricción (8) asegura que el ordenamiento inverso (*jj* antes de *j*) no sea válido. Por último, la restricción (9) asegura que para cada operación se seleccione una única velocidad.

2.2.2 Flow-shop con lot-streaming y consideraciones energéticas (SBS+EA)

Tomando como base el modelo FSS+EA, se incorpora al mismo la estrategia de lot-streaming dentro del proceso de scheduling. En este modelo cada trabajo *j*, compuesto por U_j unidades es dividido en *f* sublotes de tamaño $s_{i,j}$. Al considerar sublotes, también es necesario considerar que se empiezan a multiplicar los tiempos de traslado, ya que no ocurre una única vez para todo el lote U_j sino *f* veces (una para cada $s_{i,j}$). Por otro lado, al incorporar lot-streaming se multiplica la cantidad de veces que deben cargarse y descargarse las máquinas (una por cada sublote, en lugar de una para todo el lote), así como los tiempos de traslados o transferencias de las piezas. A continuación, se presenta sólo los índices y parámetros que se ven afectados por esta incorporación.

Índices:

I: sublotes: $i = 1, 2, \ldots, f$.

Parámetros:

f: número de sublotes.

$s_{i,j}$: tamaño del sublote *i* del producto *j* (cantidad de unidades contenidas en el sublote).

FT_j: tiempo fijo de transferencia del trabajo *j* (aplica para cada sublote sin depender de la cantidad de unidades contenidas en el mismo).

$RT_{j,k}$: tiempo de descarga asociada a la máquina *m* después de procesar un sublote del producto *j* en la máquina *k*.

Variables:

$C_{i,j,k}$: tiempo en completar el sublote *i* del trabajo *j* en la máquina *k*.

Desglose de Z (ecuación 1):

$$C'_{max} \geq C_{i,j,k} + RT_{j,k}, \forall\, j, k = m, i = f \tag{10}$$

$$TO_k = C_{max} - \sum_j \sum_i \sum_l \frac{p_{j,k}}{Vl1_l} * s_{i,j} * Y_{j,l,k}\,, \forall\, k \tag{11}$$

$$TEC' = \sum_k \sum_j \sum_i \sum_l \frac{PM_k * P_{j,k} * s_{i,j} * Vl2_l}{60 * Vl1_l} * Y_{j,l,k} + \sum_k \frac{MO_k * PM_k}{60} * TO_k \tag{12}$$

Sujeto a:

$$C_{i,j,k+1} - \frac{p_{j,k+1}}{Vl1_l} * s_{i,j} * Y_{j,k,l} \geq\ C_{i,j,k} + TS_{j,k+1} + FT_j, \forall\, j, k < m, i = 1 \tag{13}$$

$$C_{i,j,k+1} - \frac{p_{j,k+1}}{Vl1_l} * s_{i,j} * Y_{j,k,l} \geq\ C_{i,j,k} + FT_j, \forall\, j, i > 1, k < m \tag{14}$$

$$C_{i,j,k} - \frac{p_{j,k}}{Vl1_l} *\ s_{i,j} * Y_{j,k,l} \geq TS_{j,k}, \forall\, j, i = 1, k = 1 \tag{15}$$

$$C_{i,j,k} - \frac{p_{j,k}}{Vl1_l} *\ s_{i,j} * Y_{j,k,l} \geq C_{i-1,j,k}, \forall\, j, k, i > 1 \tag{16}$$

$$C_{ii,jj,k} - \frac{p_{jj,k}}{Vl1_l} * s_{ii,jj} * Y_{jj,k,l} - TS_{jj,k} + G * \left(1 - X_{j,jj}\right) \geq C_{i,j,k} + RT_{j,k}, \forall\, j, jj, k, ii = 1, i = I, j \neq jj \tag{17}$$

El cálculo de C_{max} ahora considera la finalización del último sublote procesado en la última máquina *m* (ecuación 10). También el tiempo ocioso se modifica (ecuación 11), ya que las operaciones son dependientes del tamaño del sublote $s_{i,j}$. Lo mismo para el total de energía consumida (ecuación 12). Al incorporar el lot-streaming se modifican algunas restricciones del problema. En la restricción (13) se secuencia el primer sublote del trabajo *j*, y se contemplan los tiempos de traslado entre dos máquinas consecutivas. En la restricción (14) se verifica que cada sublote respete la precedencia de operaciones del flow-shop. En la restricción (15) se cumple con la capacidad requerida en la primera máquina por el primer sublote. El ordenamiento de los sublotes de un mismo trabajo *j* se obtiene por la restricción (16). Sin embargo, al no permitir entremezcla, el secuenciamiento entre trabajos se realiza por la misma variable que en el modelo anterior, aunque en este caso la restricción (17) incorpora la proporcionalidad de los procesamientos según $s_{i,j}$.

2.2.3 Flow-shop con lot-streaming, velocidad indexada en los sublotes y consideraciones energéticas (SBSI+EA)

En este modelo, además de incluir la estrategia de lot-streaming como división de lotes de producción, también se lo incorpora en la decisión sobre la velocidad de procesamiento (SBSI+EA). Tomando como base el modelo SBS+EA, se incorpora una nueva variable para definir las velocidades de procesamiento.

Variables:

$Y_{i,j,k,l}$: variable binaria, es 1 si el sublote *i* del trabajo *j* se procesa a la velocidad *l* en la máquina *k*, 0 en otro caso.

Desglose de Z (ecuación 1):

$$TO_k = C_{max} - \sum_j \sum_i \sum_l \frac{p_{j,k}}{Vl1_l} * s_{i,j} * Y_{i,j,l,k}, \forall\, k \tag{18}$$

$$TEC' = \sum_k \sum_j \sum_i \sum_l \frac{PM_k * p_{j,k} * s_{i,j} * Vl2_l}{60 * Vl1_l} * Y_{i,j,l,k} + \sum_k \frac{MO_k * PM_k}{60} * TO_k \tag{19}$$

Sujeto a:

$$C_{i,j,k+1} - \frac{p_{j,k+1}}{Vl1_l} * s_{i,j} * Y_{i,j,k,l} \geq C_{i,j,k} + TS_{j,k+1} + FT_j, \forall\, j, k < m, i = 1 \tag{20}$$

$$C_{i,j,k+1} - \frac{p_{j,k+1}}{Vl1_l} * s_{i,j} * Y_{i,j,k,l} \geq C_{i,j,k} + FT_j, \forall\, j, i > 1, k < m \tag{21}$$

$$C_{i,j,k} - \frac{p_{j,k}}{Vl1_l} * s_{i,j} * Y_{i,j,k,l} \geq TS_{j,k}, \forall\, j, i = 1, k = 1 \tag{22}$$

$$C_{i,j,k} - \frac{p_{j,k}}{Vl1_l} * \ s_{i,j} * Y_{i,j,k,l} \geq C_{i-1,j,k}, \forall\, j,k,i > 1 \tag{23}$$

$$C_{ii,jj,k} - \frac{p_{jj,k}}{Vl1_l} * s_{ii,jj} * Y_{ii,jj,k,l} - TS_{jj,k} + G * \left(1 - X_{j,jj}\right) \geq C_{i,j,k} + RT_{j,k}\ , \forall\, j, jj, k, ii = 1, i = I, j \neq jj \tag{24}$$

$$\sum_{l} Y_{i,j,k,l} = 1, \forall\, j,k \tag{25}$$

El tiempo ocioso TO_k se modifica (ecuación 18), al incorporar la variable $Y_{i,j,k,l}$. Lo mismo ocurre con el consumo energético (*TEC*) (ecuación 19). Luego, las restricciones (20) - (25) tienen una interpretación similar a la del modelo SBS+EA, con la diferencia de que ahora la duración de los procesamientos se puede modificar para cada sublote *i* de cada trabajo *j*. Este último modelo, naturalmente, incluye un aumento en la cantidad de las variables binarias, lo que dificulta su resolución.

3 Experimentación

El diseño experimental busca comparar los modelos y mostrar empíricamente si la incorporación de lot-streaming es ventajosa a la hora de abordar problemas de scheduling en flow-shop con consideraciones energéticas. Para ello, se tomaron como punto de partida los trabajos que han utilizados enfoques similares [7] [10]. Respecto a la parametrización relacionada al lot-streaming se siguió a Rossit et al. [13] y Ferraro et al. [14]. Los tamaños de los problemas estudiados consideraron 5 y 10 máquinas, y se utilizaron 3, 5 y 7 trabajos para cada cantidad de máquinas. Por otro lado, para los parámetros definidos en la sección 2.1 para los distintos modelos se utilizó la siguiente parametrización:

U_j: aleatorio uniforme entre [4;24]*5. Entonces, los lotes de cada trabajo *j* quedan entre 20 y 120 como en [10].

$s_{i,j}$: se calcula dividiendo el valor de U_j entre los 5 sublotes para cada conjunto de datos.

$TS_{j,k}$: aleatorio uniforme entre [1;25].

$P_{j,k}$: aleatorio uniforme entre [1;5] ya que es tiempo unitario para unidad del lote U_j.

FT_j: aleatorio uniforme entre [1;4].

$RT_{j,k}$: aleatorio uniforme entre [2;6].

$Vl1_l$: toma algunos de los tres valores siguientes (1.2, 1, 0.8). Este factor se aplica al $P_{j,k}$, por lo que puede hacer en tiempo estándar (1), más rápido (1.2) o más lento (0.8).

$Vl2_l$: toma algunos de los tres valores siguientes (1.5, 1, 0.6). Dependiendo del valor de $Vl1_l$ seleccionado respectivamente.

MO_k: 0.05.

PM_k: 60 KW.

Para cada tamaño del problema se generaron 5 conjuntos de datos. Cada uno de estos conjuntos de datos fue resuelto por los tres modelos. Las experimentaciones se realizaron en una computadora AMD A6-7310 APU with AMD Radeon R4 Graphics con 8gb de RAM. Todos los modelos fueron implementados en Pyomo [17] y como solver se utilizó GUROBI 8.1.1. Para el post procesamiento de datos se utilizó SolverStudio [18].

4 Comparación de resultados

En la tabla 1 se muestran los valores promedios obtenidos para cada problema considerando cada uno de los modelos (FSS+EA, SBS+EA y SBSI+EA). Los resultados se expresaron según los términos, C_{max} y *TEC*. En la tabla, se puede observar que en todos los casos los modelos que consideran lot-streaming (SBS+EA y SBSI+EA) superan al modelo que no lo considera (FSS+EA), tanto en el C_{max} como en el *TEC*. En términos de C_{max} estas diferencias son muy notorias, ya que por ejemplo para el problema 5J-5M, el modelo FSS+EA obtiene un C_{max} promedio de 2173, mientras que el modelo SBS+EA lo reduce a 1472, y el modelo SBSI+EA lo lleva a 1462. Esta tendencia se mantiene para todos los problemas. Por el lado del *TEC*, se observa el mismo comportamiento, el modelo FSS+EA es el de peor desempeño, mientras que SBS+EA mejora sobre FSS+EA, y el mejor de los tres modelos es el SBSI+EA.

Tabla 1. Valores promedio obtenidos realizando 5 corridas por modelo y por instancia.

Problemas	C_{max}			*TEC*		
	FSS+EA	**SBS+EA**	**SBSI+EA**	**FSS+EA**	**SBS+EA**	**SBSI+EA**
3J-5M	1988	1170	1154	4522	4055	3865
3J-10M	2940	1367	1323	7984	6676	6534
5J-5M	2173	1472	1462	6007	5753	5420
5J-10M	3461	1785	1746	11267	10056	9724
7J-5M	2302	1510	1508	6349	6014	5648
7J-10M	3642	2095	2080	13218	12036	11562

Para analizar mejor los beneficios que reporta la incorporación del subloteo sobre este problema se presenta la tabla 2. En esta tabla, se muestran las diferencias porcentuales de mejora para C_{max} y *TEC*, tomando como base el resultado obtenido por el modelo FSS+EA. La tabla permite dimensionar mejor el impacto de lot-streaming sobre el problema de flow-shop con consideraciones energéticas. Ya que, en términos de makespan, en todos los casos las mejoras de los modelos SBS+EA y SBSI+EA sobre el FSS+EA superan al 30% de reducción, incluso llegando a mejoras por encima del 50% para el problema 3J-10M. Estos resultados condicen con los mostrados en la literatura de lot-streaming, en donde al permitir solapar actividades es posible reducir el makespan.

Tabla 2. Porcentaje de mejora de los modelos SBS+EA y SBSI+EA con respecto a FSS+EA.

Problemas	C_{max}		*TEC*	
	SBS+EA	**SBSI+EA**	**SBS+EA**	**SBSI+EA**
3J-5M	41,20%	42,00%	10,30%	14,50%
3J-10M	53,50%	55,00%	16,40%	18,20%
5J-5M	32,30%	32,70%	4,20%	9,80%
5J-10M	48,40%	49,50%	10,70%	13,70%
7J-5M	34,40%	34,50%	5,30%	11,00%
7J-10M	42,50%	42,90%	8,90%	12,50%

Sin embargo, los resultados relativos al *TEC* son también alentadores, ya que lot-streaming permite reducir el consumo energético de forma simultánea junto con el makespan. A su vez, estas reducciones del *TEC* también son significativas, alcanzando valores por encima del 16% para el SBS+EA y del 18% para el SBSI+EA para el problema 3J-10M. La reducción mínima que alcanza el lot-streaming es del 4% (SBS+EA) para el problema 5J-5M, lo que sigue siendo un valor representativo, ya que la implementación de lot-streaming no implica una inversión en capital para mejorar la capacidad instalada. Mientras que reducir el consumo energético, sí constituye una reducción directa en los costos.

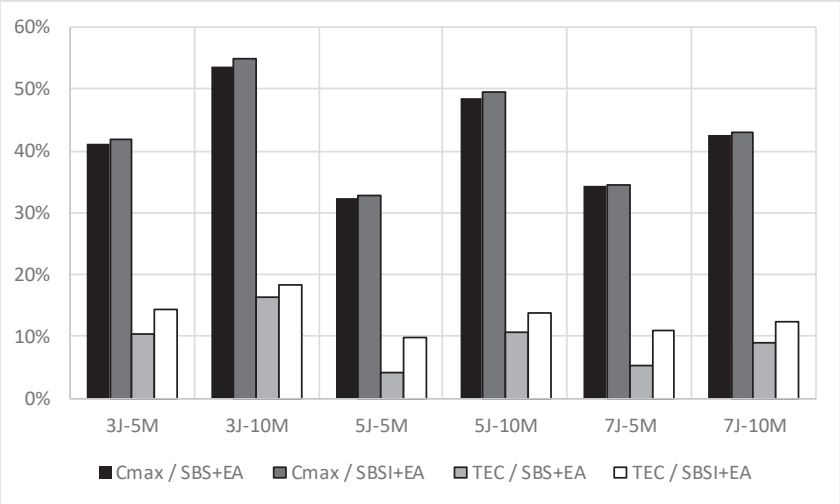

Fig. 1. Porcentaje de mejora de los modelos SBS+EA y SBSI+EA con respecto a FSS+EA.

Finalmente, para visualizar mejor el comportamiento de los modelos que consideraron lot-streaming sobre el flow-shop clásico, se presenta la figura 1. En ella se observan gráficamente los valores de la tabla 2. Se pueden apreciar los beneficios que traen la

incorporación de lot-streaming, así como los beneficios de permitir la selección de velocidad de procesamiento según el sublote. Respecto a incorporar lot-streaming es clara la ventaja tal como se comentó anteriormente, siendo el impacto en términos porcentuales, mucho más pronunciado para el makespan que para el consumo energético. Por otro lado, es posible ver que considerar la selección de la velocidad de procesamiento según el sublote (SBSI+EA), no mejora significativamente el makespan sobre no hacerlo (SBS+EA). Mientras que para el consumo energético si lo logra hacer.

Por otro lado, en la Tabla 3 se presentan los resultados sobre las velocidades, en promedio, más veces seleccionadas para tamaño de problema. Lo que se observa en la Tabla 3 es que, en términos generales, la velocidad más veces seleccionada es la 3, es decir, la velocidad de procesamiento más lenta. Sólo hay algunas excepciones para el modelo FSS+EA, es decir el que no utiliza sublotes. Mientras que para los modelos que se permiten los sublotes, la velocidad 3 es casi la selección unánime. Naturalmente, lo que se puede inferir a partir de estos resultados es que lot-streaming permite reducir el makespan de forma significativa. Ya que para el caso en que no se puede dividir la producción en sublotes (FSS+EA), hay alternancias entre la velocidad 1 (la más rápida, por ende, la que mejor makespan arroja, pero la que más consumo energético demanda), y la velocidad 3 (la que peor makespan permite, pero mejor consumo energético demanda). Sin embargo, cuando se puede dividir la producción en sublotes, como en los casos SBS+EA y SBSI+EA, la velocidad 3 es la que más veces se obtiene. Es decir, que lot-streaming permite reducir el makespan y el sistema puede abocarse a minimizar el consumo energético. No obstante, estos comentarios no son concluyentes.

Tabla 3. Valores promedio de las velocidades seleccionadas para los modelos: 1 = velocidad más rápida, 2 = velocidad intermedia y 3 = velocidad más lenta.

Problemas	FSS+EA	SBS+EA	SBSI+EA
3J 5M	1	3	3
3J 10M	3	3	3
5J 5M	3	1;3 (igual cantidad de veces)	3
5J 10M	1	3	3
7J 5M	3	3	3
7J 10M	1	3	3

En la Tabla 4, se presentan los tiempos de procesamiento que demandaron en promedio cada modelo para resolver los distintos problemas. Estos tiempos están medidos en segundos, y se consideró como tiempo límite 3.600 segundos. En los casos en que alcanzó el tiempo límite, se registró el GAP que registró el solver. De los datos mostrados en la Tabla 4, se observa el impacto computacional que tiene el lot-streaming. Ya que ambos modelos SBS+EA y SBSI+EA tienen tiempos de CPU ampliamente superiores a los del modelo FSS+EA. Incluso, el modelo SBSI+EA, que incorpora la decisión de la selección de velocidad de procesamiento a nivel del sublote, alcanza el límite de los 3.600 segundos a partir de los 5J y 10M.

Tabla 4. Valores promedio de los tiempos de procesamiento medidos en segundos. El tiempo límite es 3600 segundos. En paréntesis el GAP alcanzado el tiempo límite.

Problemas	FSS+EA	SBS+EA	SBSI+EA
3J 5M	< 1	2	795
3J 10M	1	8	2944
5J 5M	8	38	2939
5J 10M	28	1332	3600 (9,04%)
7J 5M	1806	2629	3600 (27,83%)
7J 10M	2574	3600 (6,69%)	3600 (16,86 %)

5 Conclusiones

En este trabajo se abordó un problema de scheduling en sistemas flow-shop con consideraciones energéticas. Este problema, de relevancia creciente en los últimos años, fue abordado con estrategias de lot-streaming, lo cual permite fraccionar el lote de trabajo de forma tal que se puedan solapar las actividades. Esta estrategia permite explotar la eficiencia de los sistemas productivos. En este trabajo, se la implementó con éxito. Se logró reducir de forma simultánea tanto el makespan como el consumo energético. Las reducciones logradas son más que significativas considerando que se trata únicamente de una estrategia de secuenciamiento, que no implica una inversión en capital para mejorar la capacidad instalada. Además, se comprobó que permitir variar la velocidad de procesamiento para cada sublote procesado profundizaba los beneficios en términos de consumo energético. No obstante, esta última opción trae aparejado un fuerte incremento en el costo computacional, por lo que a futuro se propone trabajar en métodos más eficiente de cálculo, como diseño de métodos heurísticos.

Resumo Este trabalho lida com um problema integrado de localização de facilidades e sequenciamento da produção. O problema consiste na escolha de onde localizar p máquinas, dentre um conjunto finito de possibilidades e em sequenciar um conjunto de tarefas nessas máquinas de modo a minimizar o *makespan*. Cada tarefa possui uma *release date* dependente da localização e um tempo de processamento. Dessa forma, as decisões associadas com a localização das máquinas têm um impacto direto nas decisões do sequenciamento da produção, justificando a resolução integrada dos problemas. Para resolver este problema integrado, uma formulação matemática indexada no tempo e um algoritmo de busca local iterada são propostos. Os algoritmos foram avaliados e comparados com métodos propostos na literatura através de experimentos computacionais. Os resultados obtidos mostram que os métodos propostos apresentam desempenho melhores que os métodos da literatura, sendo capazes de achar soluções ótimas para 1399 das 1450 instâncias testadas.

Keywords: sequenciamento da produção, localização de facilidades, formulação indexada no tempo, busca local iterada, makespan

1 Introdução

Problemas de localização de facilidades e sequenciamento de tarefas são problemas bastante estudados na área de otimização combinatória. A principal motivação para estudá-los vem da possibilidade de aplicação em diversos contextos (como logística, gestão de projetos, planejamento da produção, processamento de dados, etc.), bem como do desafio em gerar soluções eficientes, pois muitos deles pertencem a classe de problemas NP-Difícil ([2, 12, 17, 18]). Desde a década de 60 muitos artigos científicos foram publicados nestes temas, porém poucos deles abordaram os problemas de maneira integrada.

Neste contexto, o problema *ScheLoc* combina o sequenciamento de tarefas com a localização de facilidades em um único e integrado problema. O *ScheLoc*

consiste em selecionar os locais de p máquinas e em sequenciar um conjunto de tarefas a serem processadas nestas máquinas. Para processar uma tarefa, a mesma deve ser transportada (e.g., de um armazém ou fornecedor externo) para o local da máquina que irá processá-la. O tempo necessário para realizar este transporte define o tempo mais cedo que as tarefas estarão disponíveis para serem processadas em cada máquina (ou local). Possíveis aplicações do problema de *ScheLoc* incluem, e.g., a utilização de máquinas móveis cujo o posicionamento pode variar de acordo com o objetivo do sequenciamento, a localização de trituradores para processamento de minerais, a escolha do melhor posição para atracar um navio a ser carregado e a localização de dispositivos de treinamento para forças militares ([3, 5–8]).

O foco deste artigo está no estudo de uma variante do *ScheLoc* em que i) os locais candidatos para localização das p máquinas está restrito à um conjunto discreto, ii) as máquinas são consideradas idênticas e operam em paralelo, e iii) o objetivo consiste na minimização do makespan (i.e., tempo de término da última tarefa). Este problema é conhecido na literatura por *discrete parallel machine makespan ScheLoc problem* (DPMMSP). Para solucionar o problema, uma nova formulação matemática (indexada no tempo) e um algoritmo baseado na metaheurística de busca local iterada são propostos. Experimentos computacionais são realizados em um conjunto de 1450 instâncias da literatura e diversas soluções ótimas são encontradas pela primeira vez.

O restante do trabalho está organizado da seguinte maneira. A Seção 2 apresenta uma breve revisão da literatura. Uma descrição formal do DPMMSP bem como a formulação proposta são apresentadas na Seção 3. O algoritmo heurístico é detalhado na Seção 4. Os experimentos computacionais e os resultados obtidos são reportados na Seção 5. Por fim, as conclusões e sugestões de trabalhos futuros são apresentados na Seção 6.

2 Revisão da literatura

O *ScheLoc* foi introduzido na literatura em [5] com o objetivo de minimizar o *makespan*. Nesta primeira versão, os autores consideraram apenas uma máquina que poderia ser localizada em qualquer lugar em uma rede (i.e., em nós ou arestas). Kaufmann [9] também estudou o problema de *ScheLoc* para uma única máquina, porém considerando diferentes funções objetivos. Kalsch e Drezner [8], por outro lado, estudaram a versão em que uma única máquina poderia ser localizada em qualquer local de um plano do $\mathbb{R}^2$ para minimizar o *makespan* ou o tempo total de término das tarefas. Vale frisar que, uma vez que o local da máquina esteja definido, a resolução dos problemas de *ScheLoc* mencionados se reduzem ao problema de sequenciamento de uma única máquina com *release dates* $(1|r_j|C_{\max})$, que pode ser resolvido na otimalidade em tempo polinomial com por meio da regra do *earliest release date* (ERD) ([1, 13, 18]).

O DPMMSP foi proposto por Hessler e Deghdak [6] e difere das versões anteriores ao considerar p máquinas paralelas cujas localizações devem ser selecionadas de um conjunto discreto de locais candidatos. Além das decisões de

localização, o DPMMSP envolve a alocação de tarefas à locais (ou máquinas) e o sequenciamento de tarefas em p máquinas. Para resolver o problema, os autores propuseram uma formulação matemática, procedimentos para obtenção de *lower bounds* e algumas heurísticas baseadas em algoritmos de clusterização combinadas com procedimentos de busca local baseada na regra do ERD. Mais recentemente, Wang *et al.* [21] apresentaram uma formulação de fluxo em redes e três procedimentos heurísticos para solucionar o DPMMSP. Baseado em experimentos computacionais, os autores mostraram que dentro de um tempo limite de uma hora a formulação proposta é capaz de resolver mais instâncias que a formulação apresentada em [6], porém limitados à instância com menos de 20 tarefas. No tocante às soluções heurísticas, os resultados também são melhores que os reportados em [6], mas os *gaps* percentuais para os melhores *lower bounds* ainda são considerados grandes (cerca de 9% na média).

Uma versão similar ao DPMMSP foi estudada em [14], porém considerando máquinas paralelas não relacionadas. Um algoritmo mémetico baseado em busca tabu foi proposto para resolver o problema de maneira integrada. Moutrou-se, por meio de experimentos computacionais, que a abordagem integradas apresentava resultados melhores que uma abordagem sequencial (i.e., que resolver os problemas de localização e sequenciamento um após o outro, de maneira independente). Além disso, os autores resolveram instâncias do DPMMSP e os resultados obtidos foram melhores que os reportados por [6].

Outros trabalhos interessantes que merecem ser mencionados incluem o estudo de caso de [10] em uma indústria têxtil belga – onde são consideradas a possibilidade de múltiplas máquinas em um mesmo local (com locais já definidos) e, não só *release dates*, como também *due dates* – e os trabalhos de [15] e [11] que consideram incertezas nos tempos de processamento das tarefas.

3 Descrição do problema

O DPMMSP considera um conjunto $J = \{1, \ldots, n\}$ de tarefas a serem sequenciadas em no máximo p máquinas idênticas (em paralelo), cujas localizações devem ser escolhidas de um conjunto discreto $M = \{1, \ldots, m\}$ de locais candidatos (com $p < m$). Cada tarefa $j \in J$ tem que ser processada por p_j unidades de tempo por uma das p máquinas, sem interrupção, e apenas uma máquina pode ser localizada em um local candidato de M. Além disso, uma tarefa j só pode ser processada em um local k a partir de um determinado tempo r_{jk} (i.e., *release date*) que representa, por exemplo, o tempo associado ao transporte da matéria-prima necessária para executar a tarefa até o local do processamento. Os conjuntos J e M e os valores de p, p_j ($\forall j \in J$) e r_{jk} ($\forall j \in J$, $\forall k \in M$ são dados do problema. O objetivo consiste em minimizar o *makespan*, i.e., o tempo de término de processamento da última tarefa. O DPMMSP é um problema NP-Difícil pois generaliza o problema de sequenciamento em máquinas paralelas que é NP-Difícil ([4]). Um exemplo ilustrativo de uma instância com $m = 3$, $n = 6$ e $p = 2$ e uma possível solução são apresentadas na Figura 1, onde as duas máquinas são alocadas aos locais 1 e 3; as tarefas 5, 1 e 6 são processadas

no local 1; e as tarefas 4, 3 e 2 são processadas no local 3. Os tempos de início de cada tarefa são mostrados no gráfico de Gantt na parte inferior.

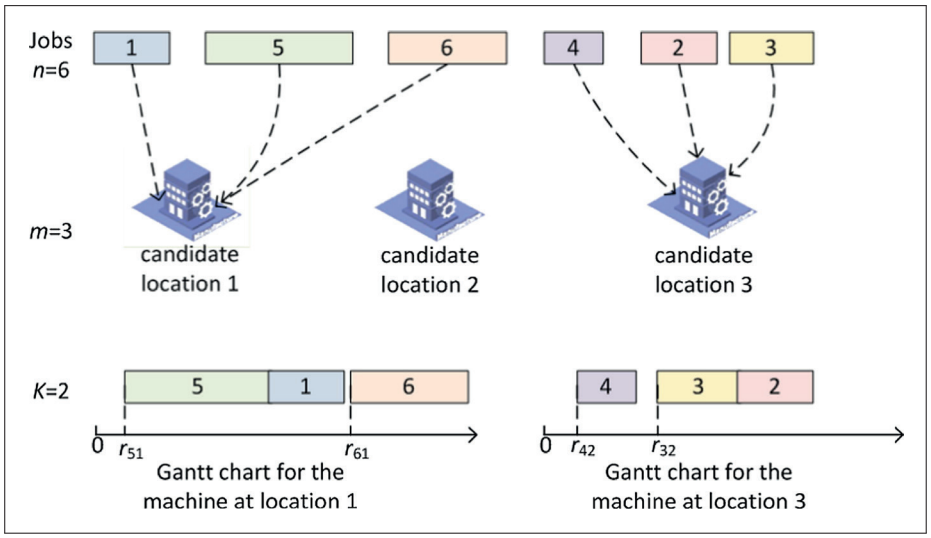

Figura 1: Exemplo gráfico de uma instância do DPMMSP e uma possível solução. Fonte: [21].

3.1 Formulação indexada no tempo

Nesta seção, apresentamos uma formulação baseada em programação inteira mista para o DPMMSP. A formulação proposta é uma adaptação da formulação indexada no tempo (TI, do inglês *Time-Indexed*) originalmente proposta por [19] para o problema de sequenciamento em uma máquina sujeito a restrições quanto à disponibilidade de recursos. Inicialmente, seja $H = \{0, 1, \ldots, T\}$ o conjunto discretizado de tempos, onde T é um limite superior para o tempo de término da última tarefa (i.e., *makespan*). Para modelar o DPMMSP por meio de uma formulação TI, considere a variável binária x_{jkt} que assume valor 1 se a tarefa $j \in J$ é processada por uma máquina localizada na localidade $k \in K$ e começa a ser processada no tempo $t \in H$, caso contrário assume o valor 0. Considere ainda a variável binária $y_k, k \in M$, que assume o valor 1 se a localidade k é selecionada para a instalação de uma máquina, ou 0 caso contrário; e a variável contínua $C_{\max}$ que representa o *makespan*. Considerando essas definições, a formulação TI para o DPMMSP é definida como se segue:

$$\text{(TI)} \quad \min \quad C_{\max} \tag{1}$$

s.a.

$$\sum_{k\in M}\sum_{t\in H} x_{jkt} \geq 1 \qquad j \in J, \tag{2}$$

$$\sum_{j\in J}\sum_{s=\max\{r_{jk};t-p_j+1\}}^{\min\{t;T-p_j\}} x_{jks} \leq y_k \qquad k \in M, t \in H, \tag{3}$$

$$\sum_{k\in M}\sum_{t\in H}(t+p_j)\, x_{jkt} \leq C_{\max} \qquad j \in J, \tag{4}$$

$$\sum_{k\in M} y_k \leq p, \tag{5}$$

$$C_{\max} \leq T, \tag{6}$$

$$y_k \in \{0,1\} \qquad k \in M, \tag{7}$$

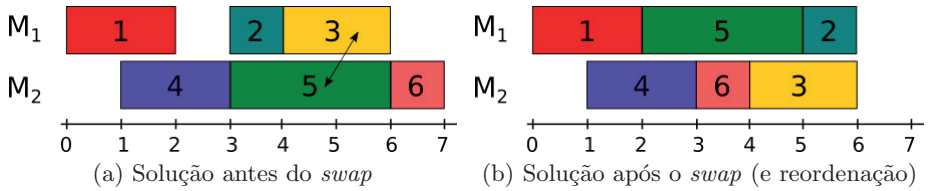
$$x_{jkt} \in \{0,1\} \qquad j \in J, k \in M, t \in \{r_{jk}, ..., T-p_j\}. \tag{8}$$

A função objetivo (1) busca a minimização do *makespan*. As Restrições (2) forçam que cada tarefa $j \in J$ seja processada ao menos uma vez. As Restrições (3), por sua vez, garantem que as tarefas sejam processadas apenas nas localidades selecionadas, ou seja, naquelas em que existam máquinas instaladas, e que essas máquinas não processem mais de uma tarefa ao mesmo tempo. As Restrições (4) dizem que o *makespan* deve ser maior ou igual aos tempos de término de todas as tarefas, enquanto a Restrição (5) indica que no máximo p localidades devem ser escolhidas. Por fim, as Restrições (6)–(8) se referem ao domínio das variáveis.

4 Algoritmo heurístico

O algoritmo desenvolvido para solucionar o DPMMSP apresentado na Seção 3 se baseia na metaheurística de busca local iterada (ILS, do inglês *Iterated Local Search*). A ILS já foi utilizada para resolver com sucesso diversos problemas de otimização, incluindo os problemas de sequenciamento e de localização de facilidades ([16]).

A ILS é composta de quatro componentes principais: i) um método construtivo para gerar a solução inicial; ii) um procedimento de busca local para explorar soluções vizinhas; iii) um mecanismo de perturbação que permite escapar de ótimos locais e favorece a busca por ótimos locais em outras regiões do espaço de busca; e iv) um critério de aceitação que decide se uma solução incumbente deve ser substituída por uma solução vizinha (para mais detalhes, ver [16]). O algoritmo proposto executa a metaheurística ILS por n_{iter} vezes, conforme mostrado no Algoritmo 1.



Uma abordagem sequencial é utilizada na geração da solução inicial. Inicialmente, selecionam-se os p locais, depois é realizada a alocação de tarefas aos locais (máquinas) selecionados e, por fim, resolve-se o sequenciamento. Para evitar a repetição da mesma solução incial nas n_{iter} reinicializações do algoritmo, o procedimento de solução inicial implementado escolhe os p locais de maneira aleatória. Para descrever o procedimento de alocação, seja M' o conjunto dos p

Algoritmo 1: BUSCA LOCAL ITERADA COM REINICIALIZAÇÃO

```
1  s_best ← ∅
2  f(s_best) ← ∞
3  para i = 1 to n_iter faça
4      s_i ← s ← ObtemSolucaoInicial()
5      iterILS ← 1
6      enquanto iterILS ≤ n_ils faça
7          s ← BuscaLocal(s)
8          se f(s) < f(s_i) então
9              s_i ← s
10             iterILS ← 0
11         s ← Perturbacao(s_i)
12         iterILS ← iterILS + 1
13     se f(s_i) < f(s_best) então
14         s_best ← s
15 retorna s_best
```

locais selecionados, LJ a lista de tarefas não alocadas e $\bar{s}$ uma solução incompleta (em construção). Para cada local $k \in M'$, identifica-se a tarefa $j' \in LJ$ que puder iniciar seu processamento o mais cedo possível (i.e., considerando o release date e o tempo de término da última tarefa sequenciada em k na solução $\bar{s}$) e insere-se o par (k, j') numa lista CL de alocações candidatas. Então, escolhe-se a alocação $(k^*, j^*) \in CL$ que levar ao menor tempo de término, remove-se a tarefa j^* da lista LJ e esvazia-se CL. O procedimento é repetido até que a lista LJ se torne vazia. Uma vez que todas as tarefas tiverem sido alocadas à uma máquina (ou local), o sequenciamento é resolvido por meio da regra do menor *release date* (ERD).

Após obtida a solução incial, uma busca local baseada em movimentos *swap* entre duas tarefas alocadas a máquinas distintas é realizada. Porém, ao invés de simplesmente realizar a troca de posições, as tarefas são posicionadas na melhor posição do sequenciamento por meio da regra ERD, como ilustrado na Figura 2.

(a) Solução antes do *swap* (b) Solução após o *swap* (e reordenação)

Figura 2: Exemplo de movimento *swap* com reordenamento baseado na regra ERD. Dados da instância: n=6, m=3, p=2, tempos_de_processamento=$[2, 1, 2, 2, 3, 1]$, *release_dates*=$[[0, 3, 4], [3, 3, 5], [4, 4, 5], [2, 1, 4], [2, 2, 4], [6, 3, 3]]$.

Para tornar a busca local eficiente, utilizamos uma estrutura de dados auxiliar que armazena a melhor posição que cada tarefa $j \in J$ pode ser sequenciada em cada máquina $k \in M'$. Além disso, para cada subsequência σ de tarefas consecutivas, armazenamos o tempo total de processamento $P(\sigma)$ e o tempo mais cedo que ela pode iniciar seu processamento $E(\sigma)$. Para uma subsequência σ_j^k contendo uma única tarefa j sequenciada na máquina k, $P(\sigma_j^k)$ e $E(\sigma_j^k)$ são iguais a p_j e r_{jk}, respectivamente. Para subsequências maiores, tais valores são calculados por concatenação de subsequências menores, conforme as equações (9) e (10) abaixo ([20]).

$$P(\sigma' \oplus \sigma'') = P(\sigma') + P(\sigma'') \tag{9}$$

$$E(\sigma' \oplus \sigma'') = \max\{E(\sigma'') - P(\sigma'), E(\sigma')\} \tag{10}$$

Com o uso das estruturas de dados auxiliares mencionadas, os custos das soluções avaliadas durante a busca local podem ser calculados em tempo constante. De modo a exemplificar o uso destas estruturas, seja ρ_{jk} a posição atual da tarefa j no sequenciamento da máquina k, ρ'_{jm} a melhor posição em que a tarefa j pode ser sequenciada na máquina m, e σ_j^k uma subsequência contendo apenas a tarefa j na máquina k. Ao considerar o *swap* entre as tarefas j e l, inicialmente alocadas às máquinas k e m, respectivamente, os tempos de término da máquinas k e m podem ser calculados efetuando-se um conjunto de concatenações. A depender das posições ρ'_{jm} e ρ_{lm} as concatenações necessárias para obter o tempo de término da máquina m podem ser efetuadas de 14 maneiras distintas, conforme ilustrado na Figura 3. O tempo de término da máquina k pode ser calculado de maneira similar.

Por fim, após encontrar o ótimo local, executa-se o procedimento de perturbação. Tal procedimento efetua trocas aleatórias de um local selecionado $k \in M'$ com um local não selecionado $m \in M \setminus M'$, iterativamente. Basicamente, para $i = 1, \ldots, p$, move-se o sequenciamento associado ao i-ésimo local (máquina) para um local de $M \setminus M'$, escolhido aleatoriamente, e atualiza-se o conjunto M'. Após efetuar as trocas de locais, os sequenciamentos de cada máquina (local) é atualizado de acordo com a regra do ERD.

5 Experimentos computacionais

Com o intuito de avaliar os algoritmos e modelos apresentados, experimentos computacionais foram executados em um computador equipado com um processador Intel Core i7-7500U de 2.70 GHz, com 12GB de memória RAM e sistema operacional Windows 10. Os algoritmos foram implementados em C++ e executados usando apenas uma *thread*. Para a resolução do modelo matemático foi utilizado o *solver* Gurobi 7.5.1.

Para avaliar o desempenho dos métodos propostos, foi considerado o conjunto de instâncias criado por [6] que está disponível para *download* em: https://drive.google.com/open?id=0B_-MYN0r5mjqOEdGSEhoLW9Ubk0. Este conjunto é dividido em quatro subconjuntos de modo que os dois primeiros são

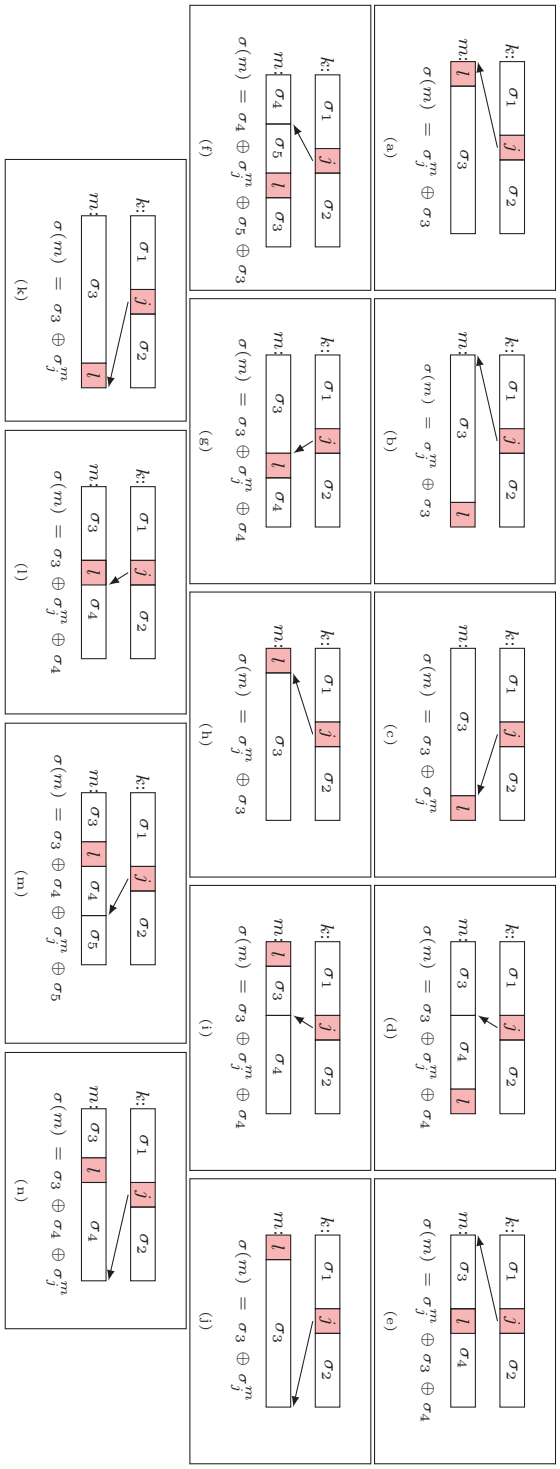


Figura 3: Possíveis concatenações ao mover a tarefa j da máquina k para a máquina m.

compostos por instâncias geradas randomicamente, o terceiro subconjunto é composto por instâncias criadas baseadas em uma rede criada a partir de elementos aleatórios, e o quarto contém instâncias em que as localidades candidatas são escolhidas aleatoriamente dentro de uma área quadrada. Um resumo com as características principais de cada subconjunto de instâncias é mostrado na Tabela 1 a seguir:

Tabela 1: Principais características das instâncias

conjunto	nome	estrutura	#inst.	n	m	p	r_{jk}	p_j
1	small	random, com $\|J\| \neq \|M\|$	50	$[2, 30]$	$[2, 10]$	$[1, 9]$	inteiro	inteiro
2	large	random, com $\|J\| \neq \|M\|$	450	$[4, 299]$	$[5, 60]$	$[2, 50]$	inteiro	inteiro
3	network	network, com $\|J\| = \|M\|^*$	350	$[10, 299]$	$[10, 299]$	$[2, 35]$	inteiro	inteiro
4	planar	planar, com $\|J\| = \|M\|^*$	600	$[10, 300]$	$[10, 300]$	$[2, 35]$	real	inteiro

* O número de locais candidatos é igual ao número de tarefas.

Os tempos de processamento e os *release dates* das tarefas são representados por valores inteiros nas instâncias dos conjuntos 1, 2 e 3, enquanto que para as instâncias do conjunto 4 os valores dos *release dates* são representados por números reais. Em particular, para as instâncias do conjunto 4, os nossos experimentos foram executados considerando valores de *release dates* arredondados para a segunda casa decimal (e multiplicando por 100, para obter valores inteiros).

Para avaliar o desempenho dos métodos propostos, dois experimentos foram realizados. O primeiro tem como o objetivo avaliar o desempenho da formulação TI (1)-(8), enquanto o segundo experimento objetiva a avaliação da metaheurística ILS proposta e descrita na Seção 4.

Com relação aos experimentos com a formulação TI, para cada instância um tempo limite de 300 segundos foi imposto para a execução do *solver*. Além disso, para cada instância o valor inicial de T, que define o horizonte de tempo para o processamento das tarefas, foi obtido através da execução do procedimento de obtenção de uma solução inicial do ILS, detalhado na da Seção 4. Como o procedimento conta com uma componente aleatória, o mesmo foi executado 10 vezes e a melhor solução foi considerada. Com relação ao ILS, o mesmo foi executado 10 vezes e os resultados obtidos são analisados de acordo com as médias e com os melhores resultados dentre as 10 execuções. Para melhor avaliar a qualidade das soluções geradas pelo o ILS, o seguinte procedimento de obtenção de um *lower bound* para instâncias do DPMMSP foi utilizado:

$$LB = \left\lceil \left(\sum\nolimits_{j \in N} p_i / p \right) \right\rceil + \min_{j \in N, k \in M} \{r_{jk}\} \tag{11}$$

Os resultados obtidos tanto para a formulação TI quanto para a metaheurística ILS são apresentados lado-a-lado nas Tabelas 2-5.

Nestas tabelas, cada linha reporta os valores médios/totais para cada grupo de instância, onde a coluna *grupo* indica os números mínimos e máximos de

tarefas das instâncias de cada grupo, a coluna *#inst* apresenta a quantidade de instâncias por grupo, as colunas *#opt* e *#lim* (apenas para as Tabelas 4 e 5) sob a coluna *TI* indicam quantas instâncias foram resolvidas na otimalidade e quantas atingiram o limite de memória sem resolver ao menos a relaxação linear, respectivamente. A coluna *gap (%)* (não se aplica à Tabela 2) mostra o gap médio para as instâncias do grupo que tiveram ao menos a relaxação linear resolvida e a coluna *tempo (s)* mostra o tempo médio de execução, em segundos, ambas sob a coluna *TI*. Para as instâncias em que a execução da formulação TI foi interrompida por limite de memória, foi considerado 300 segundos como tempo de execução (usado no cálculo dos tempos médios). As colunas *#opt* sob as colunas *ILS - resultados médios* e *ILS - melhores resultados* indicam a quantidade média de execuções do ILS que levaram à soluções ótimas e a quantidade total de soluções ótimas provadas para cada grupo de instâncias, respectivamente. As colunas *gap (%)* apresentam os gaps para os melhores *lower bounds* dentre os obtidos pela Equação (11) e pela formulação TI. Por fim, a coluna *tempo (s)* sob a coluna *ILS - resultados médios* indica a média dos tempos médios das 10 execuções do ILS para cada instância.

Tabela 2: Resultados obtidos, TI e ILS - instâncias do tipo *small*

		TI		ILS				
				resultados médios			melhores resultados	
grupo	#inst	#opt	tempo (s)	#opt	gap (%)	tempo (s)	#opt	gap (%)
(1; 5]	10	10	0.11	9.9	0.09	<0.01	10	0.00
(6; 10]	13	13	0.17	9.8	0.17	0.01	13	0.00
(11; 15]	11	11	0.21	8.4	0.94	0.01	11	0.00
(16; 20]	6	6	0.28	8.8	0.89	0.02	6	0.00
(21; 25]	5	5	0.30	10.0	0.00	<0.01	5	0.00
(26; 30]	5	5	0.61	10.0	0.00	<0.01	5	0.00
soma/média	50	50	0.28	9.49	0.35	0.01	50	0.00

Para as instâncias do tipo *small*, a formulação TI foi capaz de resolver todas as 50 na otimalidade e em menos de 0.30 segundo em média, conforme mostrado na Tabela 2. Para esse mesmo conjunto de instâncias, observa-se que o ILS também foi capaz de encontrar soluções ótimas para todas as instâncias, onde a otimalidade foi provada comparando os *upper bounds* encontrados pelo ILS com os *lower bounds* da formulaçao TI e da Equaçao *11*. Em média, o ILS necessitou de 0.01 segundo para cada execução e 9.49 entre 10 execuções levou a soluções ótimas para o problema.

Com relação às instâncias do tipo *large*, é possível observar na Tabela 3 que a formulação TI resolveu na otimalidade 407 das 450 instâncias desse conjunto, incluindo todas com até 75 tarefas. Em média, o tempo necessário para resolução das instâncias foi de aproximadamente 105 segundos. O ILS, por sua vez, encontrou resultados ótimos para 427 das 450 instâncias desse conjunto e o tempo médio de execução do algoritmo foi de apenas 1 segundo. Em particular, todas

soma/média	450	407	0.04	105.55	9.37	0.24	1.00	427	0.12

as 450 instâncias desse conjunto foram resolvidas na otimalidade, seja pela formulação TI ou pela metaheurística ILS. Comparando os resultados obtidos com os resultados obtidos pelas formulações propostas por [6] e [21] e reportados nos seus respectivos trabalhos, observa-se que a TI proposta apresentou um desempenho bem superior ao dessas formulações. A formulação proposta por [6] foi capaz de resolver apenas 26 instâncias do tipo *small*, enquanto que a formulação de [21] resolveu apenas 32 instâncias *small*. Nenhuma das duas formulações foi testada nas instâncias do conjunto *large*.

soma/média	350	242	52	0.70	203.17	9.20	0.25	3.58	324	0.19

Diferentemente das instâncias dos tipos *small* e *large*, os conjuntos *network* e *planar* são caracterizadas pelo número de locais candidatos igual ao número de tarefas, o que impacta diretamente no aumento da quantidade de variáveis

na formulação TI. Este impacto pode ser notado nos resultados mostrados nas Tabelas 4 e 5. Por outro lado, o desempenho do ILS se mantém bastante robusto. Em particular, o modelo matemático proposto por [6] foi capaz de resolver apenas duas instâncias do conjunto *network* e duas do conjunto *planar*, enquanto o modelo de [21] não foi capaz de resolver nenhuma instância desses conjuntos.

Com relação às instâncias *network*, apesar da formulação TI ter sido capaz de resolver 242 das 350 instâncias, incluindo todas com até 75 tarefas, é possível observar que nenhuma com mais de 275 teve a relaxação linear resolvida seja por ter atingido o tempo limite ou por ter estourado a memória. O ILS, por sua vez, obteve soluções provadamente ótimas para 324 das 350 instâncias, incluindo todas aquelas com mais de 175 tarefas, e com um tempo médio de execução de menos de 4 segundos. Em particular, o ILS obteve mais dificuldade nas instâncias do grupo $(51; 75]$, mesmo assim, obtendo um gap médio inferior a 2%.

No que se refere às instâncias do conjunto *planar*, apenas 9, todas com $n \leq 25$, foram resolvidas na otimalidade pela formulação TI. Para a maioria das outras instâncias, com $n > 25$, não foi possível resolver nem ao menos relaxação linear do modelo dentro dos limites de tempo e memória. O ILS, mais uma vez, mostrou-se robusto, sendo capaz de provar a otimalidade de 558 das 600 instâncias (incluindo todas com $n > 125$) desse conjunto. O tempo médio requerido por cada execução do ILS foi de cerca de 3.3 segundos.

6 Conclusões e trabalhos futuros

Neste trabalho, foram propostos algoritmos para resolver de forma eficiente um problema integrado de localização de facilidades e de sequenciamento da produção. Em particular, foram propostas uma formulação matemática baseada em variáveis indexas no tempo (TI) e um algoritmo heurístico baseado em busca

local iterada (ILS). Foi mostrado, através de experimentos computacionais, que a formulação TI teve um desempenho satisfatório e que obteve resultados melhores que os obtidos pelas formulações matemáticas da literatura propostas por [6] e [21], sendo capaz de resolver 518 das 1450 instâncias testadas. O algoritmo ILS por sua vez, se mostrou capaz de obter soluções provadamente ótimas para 1359 instâncias e de prover gaps reduzidos para as demais. Devido ao uso de estruturas de dados auxiliares que permitem a avaliação das soluções em tempo constante durante a busca local, o ILS apresentou tempos médios de execução bastante reduzidos, sempre inferiores a 10 segundos, na média. Pesquisa futuras podem ser conduzidas no sentido de propor novos algoritmos exatos (formulações matemáticas, branch-and-cut, branch-and-price) e heurísticos, além do uso integrados das duas abordagens de resolução de problemas, capazes de lidar de forma mais eficiente com as instâncias mais desafiadoras do problema. Outra linha de pesquisa interessante consiste no estudo e adaptação dos métodos propostos para outras variantes do problema estudado.

Resumen Esta investigación busca evaluar el efecto del fenómeno de aprendizaje y olvido en las decisiones de polifuncionalidad. Este fenómeno se produce cuando empleados polifuncionales pierden productividad en aquellas tareas que realizan con menor frecuencia. En la literatura se recomienda considerar esta disminución de la productividad en las decisiones de polifuncionalidad, con el fin de encontrar alternativas de planificación que mejoren el rendimiento de los empleados. La metodología de solución propone un modelo de programación entera mixta que explícitamente incorpora el fenómeno de aprendizaje y olvido y, también, el uso de personal polifuncional a través del enfoque *k-chaining*. Esta formulación permite determinar cuántos empleados deben ser polifuncionales, en cuántos departamentos adicionales serán entrenados, y qué grado de productividad se espera en cada departamento entrenado. La solución del problema minimiza los costos de subdotación, capacitación y pérdida de productividad. Nosotros presentamos un caso de estudio en la industria retail, en el cual se evaluaron dos experimentos que enfrentaron tres diferentes niveles de variabilidad en la demanda. El primer experimento, generó menores costos debido a que no incorporó la pérdida de productividad asociada al fenómeno de aprendizaje y olvido. El segundo experimento, que sí incorporó dicho fenómeno, generó un mayor costo total pero su solución se ajusta mejor a la operación real de una tienda de retail. Finalmente, dado la incorporación del fenómeno de aprendizaje y olvido, el segundo experimento requirió mayores niveles de polifuncionalidad para minimizar los costos de subdotación y, a su vez, compensar la pérdida de productividad.

Palabras claves: Aprendizaje y olvido, Chaining, Polifuncionalidad, Programación de personal, Retail.

1 Introducción

Los sectores manufactureros y de servicios presentan un rápido crecimiento, son altamente competitivos, y requieren un uso intensivo de los recursos humanos (RRHH). Estos sectores incluyen industrias tales como: automotriz, textil, manufactura, centros de llamadas, salud, retail, entre otras. Henao [1] enuncia que los RRHH son generalmente los recursos productivos más costosos. Por lo tanto, su eficiente gestión permite a las industrias de estos sectores mejorar el nivel de servicio ofrecido a sus clientes y también disminuir los costos laborales. Particularmente, la industria retail debe responder no solo ante fenómenos predecibles como la estacionalidad de la demanda sino también ante fenómenos no predecibles como la incertidumbre de la demanda y el ausentismo no programado de personal. Tales fenómenos producen periodos de sobredotación y subdotación de personal, los cuales tienden a incrementar los costos laborales y deteriorar el nivel de servicio ofrecido a los clientes [2 , 3].

Para la industria retail, varios autores han abordado los problemas de sobredotación y subdotación de personal mediante el uso de personal polifuncional [4 , 5 , 6 , 7]. Note que, el personal polifuncional es aquel que puede trabajar en k departamentos de una tienda (con $k \geq 2$), y la flexibilidad que éstos brindan permite transferir empleados de departamentos sobredotados a aquellos con subdotación de personal. Por lo tanto, su uso eficiente permite minimizar el desajuste entre la demanda y la oferta laboral. Sin embargo, la polifuncionalidad viene con un costo, especialmente en el caso de la polifuncionalidad total, por lo cual, contratar y entrenar empleados en múltiples departamentos puede ser muy costoso.

Además, producto del fenómeno conocido en la literatura como "aprendizaje y olvido", un empleado polifuncional tendrá una pérdida de productividad en aquellos departamentos en los que sea asignado con menor frecuencia. En consecuencia, este proceso de olvido y pérdida de productividad generará un costo para las empresas, ya que ante una menor productividad laboral se requerirá asignar más horas hombre para cubrir un nivel de demanda determinado. Adicionalmente, Azzi y Liang [8] explican que hay rendimientos decrecientes a escala a medida que el número de habilidades aumenta en un empleado. Por lo tanto, niveles de polifuncionalidad muy altos pueden ser imprácticos e innecesarios y, en consecuencia, también se requiere establecer políticas claras que permitan definir cuáles son los niveles de polifuncionalidad más costo-efectivos. Lo descrito hasta aquí, indica que la literatura en retail se ha concentrado principalmente en modelar los beneficios de la polifuncionalidad; sin embargo, es necesario también desarrollar modelos matemáticos que incorporen los costos asociados a la pérdida de productividad ocasionada por el fenómeno de aprendizaje y olvido.

Considerando la necesidad descrita arriba, la contribución que pretende hacer este artículo a la gestión de los recursos humanos en la industria retail, es desarrollar un modelo que determine los niveles de polifuncionalidad que minimicen los costos de entrenamiento y de subdotación de personal; pero también los costos asociados a la pérdida de productividad laboral. Por lo tanto, para un problema de asignación anual de personal, se formuló un modelo de programación entero mixto que explícitamente incorpora el fenómeno de aprendizaje y olvido. Adicionalmente, el modelo asegurará la implementación de la política de flexibilidad laboral conocida como *k-chaining*. Esta

política es ampliamente recomendada en la literatura para enfrentar una demanda incierta [5 , 6]. Bajo la política *k-chaining*, cierto número de empleados serán entrenados en *k* departamentos (con $k \geq 2$), tal que las decisiones de asignación son configuradas a través de un grafo bipartito que involucra deferentes tipos de cadenas cerradas.

Finalmente, esta metodología será aplicada a un caso de estudio en un retail chileno usando un software comercial. El desempeño del enfoque de optimización será evaluado para varios escenarios de variabilidad en la demanda, esto nos permitirá medir los beneficios de la polifuncionalidad ante una demanda incierta, pero también evaluar el impacto del fenómeno de aprendizaje y olvido.

2 Revisión de literatura

La Tabla 1 resume una serie de artículos que han estudiado el efecto de la pérdida de productividad en los problemas de programación de personal que consideran personal polifuncional. A continuación, se explican los elementos presentes en la Tabla 1:

1. *Nivel de decisión de los recursos humanos* (ND-RRHH): Indica el tipo de problema de programación de personal abordado en cada estudio. Puede ser: (i) dotación de personal (D); (ii) planificación de turnos (PT); y (iii) asignación (A). Este último problema se refiere al problema de asignación de personal, el cual es abordado en el presente estudio.
2. *Polifuncionalidad* (PF): Indica si la polifuncionalidad fue modelada cómo un parámetro (Par), o una variable de decisión (Var).
3. *Encadenamiento* (CH): Indica si el estudio evalúa o no los beneficios de la polifuncionalidad a través de la política *k-chaining*.
4. *Fuerza laboral homogénea o heterogénea* (HH): Puede ser: (i) homogénea (Hom), en donde la productividad de un empleado es la misma, independientemente del número de tareas o departamentos en los que sea asignado; y (ii) heterogénea (Het), en el que la productividad de un empleado varía cuando es capacitado para trabajar en múltiples tareas o departamentos.
5. *Modelación de la productividad* (MP): Indica cómo se modela la productividad para considerar el efecto de pérdida/ganancia ocasionado por el uso de personal polifuncional. Según Henao et al. [5] habitualmente se consideran tres tipos de enfoques: (i) aprendizaje y olvido (L/F), en donde la productividad de los empleados se modela como un proceso natural de aprendizaje, olvido y reaprendizaje (ii) matriz de productividad (M), en la cual se asume que cada empleado tiene diferentes niveles de productividad en los departamentos capacitados, lo cual se representa matricialmente; y (iii) productividad constante (E), donde todos los empleados son igualmente productivos en todos los departamentos capacitados.
6. *Costo de pérdida de productividad (CP):* Indica si en el estudio se tuvo en cuenta el costo monetario que representa la pérdida de productividad generada por la polifuncionalidad.
7. *Método* (Met)*:* Indica el método de solución usado en el estudio. Puede ser: (i) heurísticas/metaheurísticas (H); (ii) optimización (OP), (iii) simulación (S), y (iv) Analítico (AN).

8. *Horizonte de planificación (HP):* indica el horizonte de planificación abarcado en el estudio.
9. *Aplicación* (AP): Representa el sector industrial en el cual fue aplicado el estudio. Puede ser: (i) Manufactura (M); (ii) Centros de llamadas (CL); y (iii) Retail (R).

La Tabla 1 reporta varios hallazgos en la literatura dignos de destacar. Primero, pocos estudios evaluaron para la industria retail los beneficios de incorporar la polifuncionalidad laboral en la gestión de los recursos humanos [4 , 5 , 6 , 7]. Segundo, muy pocos estudios usaron la política *k-chaining* para estructurar los planes de entrenamiento de los empleados a través de cadenas cerradas [5 , 6 , 7]. Estos estudios fueron aplicados a la industria retail, y reportaron que una política *k-chaining* con *k=2* fue altamente efectiva para minimizar los costos de sobre/subdotación de personal ante escenarios de demanda incierta. Sin embargo, a diferencia del presente trabajo, tales estudios consideraron una fuerza laboral homogénea y, por lo tanto, no se incorporó el efecto de aprendizaje y olvido en los modelos. Además, utilizaron una política *k-chaining* con *k=2*, lo que significa que los empleados solo podían ser capacitados en un máximo de dos departamentos. En cambio, este trabajo usará una política *k-chaining* con $k \geq 2$ y también incorporará en la modelación matemática el proceso de aprendizaje y olvido.

Tercero, la mayoría de los estudios previos fueron aplicados al sector manufactura, y a su vez, la mayoría de éstos modelaron la productividad laboral considerando los efectos del fenómeno de aprendizaje y olvido. Esto demuestra la importancia de estudiar el fenómeno de aprendizaje y olvido, y explorar el impacto que tiene en la industria del sector de servicios, en particular en la industria retail, donde también es observado. Cuarto, la mayoría de los modelos propuestos no consideran la repercusión monetaria que se deriva cuando la productividad de un empleado disminuye a medida que aumenta su nivel de polifuncionalidad. Attia et al. [16] resalta la importancia de incorporar dicho costo en la función objetivo del problema, pues de esta manera se cuantifican mejor los costos y los beneficios asociados al uso de personal polifuncional. En consecuencia, este estudio considerará dicho costo en la función objetivo.

3 Descripción del problema

El problema consiste en diseñar un plan de capacitación idóneo para una fuerza laboral conocida, y a su vez, obtener la asignación semanal de horas de trabajo para un horizonte de planificación de 52 semanas (i.e., un año). De manera novedosa, esta formulación matemática incorporará explícitamente términos en la función objetivo y restricciones que permitan modelar una política de polifuncionalidad *k-chaining* (con $k \geq 2$) y el fenómeno de aprendizaje y olvido. En términos específicos, el reto será resolver la asignación anual de horas-hombre para una tienda de retail, que simultáneamente decide: (i) ¿Cuántos empleados serán polifuncionales?; (ii) ¿En cuántos departamentos adicionales será entrenado cada empleado polifuncional; (iii) ¿Cuántas horas semanales trabajará cada empleado en cada departamento asignado?; y (iv) ¿Cuáles serán los niveles de productividad que tendrá cada empleado en los departamentos donde ha sido entrenado? Es decir, aunque un empleado polifuncional pueda trabajar en dos o más departamentos, no en todos tendrá la misma productividad.

La formulación presentada considera los siguientes supuestos: (i) El costo de subdotación es el mismo para todos los departamentos, y representa el costo por demanda insatisfecha. (ii) Los costos de entrenamiento son los mismos para todos los departamentos. Estos dos primeros supuestos son comunes en retail [5 , 6 , 7 , 25]. (iii) No se considera el ausentismo no programado de personal. (iv) Todos los empleados deben trabajar exactamente 45 horas por semana. (v) Cada empleado está inicialmente capacitado para trabajar en un solo departamento (i.e., personal especialista), pero podría ser entrenado en cualquier departamento de la tienda. (vi) Cada empleado tiene asociado una productividad igual a 1 (i.e., 100%) en el departamento en el que está inicialmente entrenado (i.e., departamento primario). (vii) Se considerarán tres tipos de empleados, los cuales son clasificados de acuerdo su grado de experiencia: Senior, Estándar y Junior. Cada tipo de empleado tendrá un nivel de productividad inicial distinto en los departamentos donde sea entrenado adicionalmente (i.e., departamentos secundarios). Finalmente, la Tabla 2 muestra la notación usada en nuestra formulación del problema.

Tabla 2. Conjuntos, parámetros, y variables del problema abordado.

Conjuntos	
I	Empleados de la tienda, indexado por i
L	Departamentos de la tienda, indexado por l
S	Semanas, indexado por s
I_l	Empleados bajo contrato en el departamento l, $I_l \subset I$
Parámetros generales	
r_{ls}	Número de horas requeridas en la semana s y departamento l, $\forall l \in L, s \in S$
h	Número de horas semanales que un empleado debe trabajar bajo su contrato
m_i	Departamento para el cual el empleado i está inicialmente entrenado, $\forall i \in I$
u	Costo de subdotación por hora
c	Costo de entrenar un empleado para trabajar en cualquier departamento
Parámetros asociados al fenómeno de aprendizaje y olvido	
σ_{il}	Tasa de aprendizaje del empleado i en el departamento l, $\forall i \in I, l \in L$
b_{il}	Factor exponencial para el empleado i del departamento l, $\forall i \in I, l \in L$
n	Número de repeticiones de trabajo
f_{il}	Pendiente de la curva de olvido, empleado i en departamento l, $\forall i \in I, l \in L$
TA	Periodo ininterrumpido de la práctica de la habilidad
TB	Periodo de interrupción después del cual la productividad ha disminuido a su nivel inicial
ξ	Representa el cociente en los periodos TA y TB. Tal que $\xi = TB/TA$
η_{eq}	Número equivalente de repeticiones de trabajo en una fecha específica
U	Costo monetario de desarrollar la productividad de los empleados
λ_{il}	Número de repeticiones de trabajo del empleado i en el departamento l que se debieron realizar si la interrupción no hubiera ocurrido, $\forall i \in I, l \in L$
θ_{il}^{ini}	Productividad inicial del empleado i en el departamento l, al ser asignado por primera vez, $\forall i \in I, l \in L$. Varía de acuerdo si es Senior, Estándar, Junior
Variables	
x_{il}	Igual a 1 si el empleado i es entrenado en el departamento l, $\forall i \in I, l \in L$
v_i	Número de habilidades adicionales del empleado polifuncional i, $\forall i \in I$
ω_{ils}	Número de horas semanales asignadas al empleado i en el departamento l, semana s, $\forall i \in I, l \in L, s \in S$
θ_{il}^{SP}	Productividad del empleado i en el departamento l, al inicio del horizonte de planificación, $\forall i \in I, l \in L$
θ_{il}^{FP}	Productividad del empleado i en el departamento l, al final del horizonte de planificación, $\forall i \in I, l \in L$
k_{ls}	Horas de subdotación en el departamento l y semana s, $\forall l \in L, s \in S$

4 Metodología

La metodología es presentada en dos subsecciones. Con base en el artículo de Attia et al. [16], en la Subsección 4.1 se presenta un conjunto de fórmulas que permiten modelar el fenómeno de aprendizaje y olvido. Luego, usando este conjunto de fórmulas, en la Subsección 4.2 se presenta el modelo de programación entera mixto para resolver el problema antes planteado.

4.1 Modelación del fenómeno de aprendizaje y olvido

Fenómeno de aprendizaje. Según Attia et al. [16], producto del fenómeno de aprendizaje, el tiempo que requiere un empleado para realizar una tarea se reduce cada vez que éste repite dicha tarea. Este fenómeno de aprendizaje representa una evolución de la productividad, la cual puede ser medida en términos de la tasa de aprendizaje σ_{il}, su productividad inicial θ_{il}^{ini} y el tiempo ininterrumpido que realizó la actividad expresado en semanas, n. Esta evolución en la productividad debido al aprendizaje puede ser expresada por la Ecuación (1). Donde el factor exponencial b_{il} se puede calcular mediante la Ecuación (2).

$$\theta_{il}^{SP} = \frac{1}{\left[1+\left(\frac{1}{\theta_{il}^{ini}}-1\right)(n)^{b_{il}}\right]} \tag{1}$$

$$b_{il} = \frac{\log(\sigma_{il})}{\log(2)} \tag{2}$$

Fenómeno de olvido. También se debe considerar la pérdida de productividad generada por la interrupción del trabajo y transferencia de los empleados a otros departamentos. El cambio constante entre departamentos puede ocasionar que se olviden las habilidades asociadas a aquellos departamentos que son asignados con menor frecuencia. Esto se le conoce como el fenómeno de olvido, lo que ocasiona una pérdida de productividad. En este caso la evolución de la productividad se puede expresar a través de la Ecuación (3). Dicha ecuación está en función de la pendiente de la curva del olvido, f_{il}, el número de repeticiones de la habilidad antes de la interrupción expresado en semanas, η_{eq}, y el periodo de interrupción λ_{il}. Donde la pendiente de la curva del olvido f_{il} se calcula usando la Ecuación (4).

$$\theta_{il}^{FP} = \frac{1}{\left[1+\left(\frac{1}{\theta_{il}^{ini}}-1\right)\left(\eta_{eq}\right)^{b_{il}-f_{il}}\left(\eta_{eq}-\lambda_{il}\right)^{f_{il}}\right]} \tag{3}$$

$$f_{il} = -b_{il}\left(b_{il}+1\right)\left[\frac{\log(\eta_{eq})}{\log(\xi+1)}\right] \tag{4}$$

Por lo tanto, debido al fenómeno del aprendizaje y olvido, además del costo de entrenamiento y subdotación; se busca minimizar también el costo de pérdida de productividad al momento de decidir en qué departamentos adicionales deben ser capacitados los empleados.

4.2 Modelo matemático que incorpora *k-chaining* y el fenómeno de aprendizaje y olvido

El modelo de optimización puede ahora ser formulado de la siguiente manera:

$$Min \quad \sum_{i\in I}\sum_{l\in L:l\neq m_i} cx_{il} + \sum_{l\in L}\sum_{s\in S} uk_{ls} + \sum_{l\in L:l\neq m_i} U\left[\frac{\sum_{i\in I}\left(\theta_{il}^{FP}-\theta_{il}^{SP}\right)}{\sum_{i\in I}\theta_{il}^{SP}}\right]x_{il} \tag{5}$$

s.a.

$$\sum_{i\in I}\theta_{il}^{FP}\omega_{ils} + k_{ls} \geq r_{ls} \qquad \forall l\in L, \forall s\in S \tag{6}$$

$$\sum_{l\in L}\omega_{ils} = h \qquad \forall i\in I, \forall s\in S \tag{7}$$

$$\omega_{ils} \leq hx_{il} \qquad \forall i\in I, \forall l\in L, \forall s\in S \tag{8}$$

$$x_{il} = 1 \qquad \forall i\in I, \forall l\in L: l=m_i \tag{9}$$

$$v_i = \sum_{i\in L:l\neq m_i} x_{il} \qquad \forall i\in I \tag{10}$$

$$\sum_{i\in l_l} v_i = \sum_{i\in\left\{I-I_l\right\}} x_{il} \qquad \forall l\in L \tag{11}$$

$$\theta_{il}^{SP} = \frac{1}{\left[1+\left(\frac{1}{\theta_{il}^{ini}}-1\right)\left(n\right)^{b_{il}}\right]} \qquad \forall i\in I, \forall l\in L \tag{12}$$

$$\theta_{il}^{FP} = \frac{1}{\left[1+\left(\frac{1}{\theta_{il}^{ini}}-1\right)\left(\eta_{eq}\right)^{b_{il}-f_{il}}\left(\eta_{eq}-\lambda_{il}\right)^{f_{il}}\right]} \quad \forall i\in I, \forall l\in L \tag{13}$$

$$0 \le \theta_{il}^{SP} \le 1 \qquad \forall i \in I, \forall l \in L \tag{14}$$

$$0 \le \theta_{il}^{FP} \le 1 \qquad \forall i \in I, \forall l \in L \tag{15}$$

$$x_{il} \in \{0,1\} \qquad \forall i \in I, \forall l \in L \tag{16}$$

$$v_i \ge 0 \qquad \forall i \in I, \forall l \in L \tag{17}$$

$$\omega_{ils} \ge 0 \qquad \forall i \in I, \forall l \in L \tag{18}$$

$$k_{ls} \ge 0 \qquad \forall i \in I, \forall l \in L \tag{19}$$

La función objetivo (5) minimiza los siguientes costos: (i) entrenamiento; (ii) subdotación del personal; y (iii) pérdida de productividad. Las restricciones (6) y (19) producen el nivel de subdotación de personal (no negativo) asociado con cada departamento. Las restricciones (7) aseguran que cada empleado trabaje exactamente la cantidad de horas requeridas por su contrato en cada semana. Las restricciones (8) imponen que cada empleado sea asignado a trabajar solo en los departamentos para los cuales fue entrenado. Las restricciones (9) determinan el departamento en el cual está capacitado inicialmente cada empleado. Las restricciones (10) indican, para cada empleado, en cuántos departamentos adicionales fue entrenado; podría continuar como especialista o convertirse en polifuncional. Las restricciones (11) garantizan que para cada departamento *l,* el número de empleados polifuncionales que pertenecen a él, será igual a la cantidad de empleados pertenecientes a otros departamentos pero que fueron entrenados para también trabajar en el departamento *l*. Las restricciones (10) y (11) garantizan la formación de cadenas cerradas a través de un enfoque *k-chaining*. Las restricciones (12) representan la evolución de la productividad bajo el fenómeno del aprendizaje, mientras las restricciones (13) representan la evolución de la productividad bajo el fenómeno del olvido. Finalmente, las restricciones (14) - (19) definen el dominio de cada variable del problema.

5 Caso de estudio, resultados y discusión

Esta sección se subdivide en tres partes. Primero, se indican los datos usados para resolver nuestro caso de estudio. Segundo, se presentan los experimentos y métricas desempeño que permitirán evaluar el impacto de la evolución de la productividad en las decisiones de polifuncionalidad. Tercero, se presentan los resultados de la implementación de la metodología y también un análisis de resultados.

5.1 Caso de estudio

Este caso de estudio considera datos reales, procesados y simulados asociados a una tienda de retail chilena.

Datos reales. Se consideran 6 departamentos y 30 empleados contratados, i.e., $|L| = 6$ y $|I| = 30$. Tal que en cada departamento hay un número inicial de empleados especialistas I_l. Además, todos los empleados deben trabajar 45 horas a la semana, i.e., *h=45,* y el horizonte de planificación es de 52 semanas, $|S| = 52$. Respecto a los costos laborales, el costo mínimo de entrenamiento es igual a *c=US$1 semana/empleado* [5], el costo de subdotación es igual a *u=US$15/h*, y el costo asociado a la pérdida de productividad es igual a *P=US$2 semana/empleado*.

Datos procesados. Estos datos son requeridos para modelar el fenómeno de aprendizaje y olvido. Este caso de estudio considera tres tipos de empleados según su productividad inicial, estos son: Sénior, Junior y Estándar. Estos tendrán una productividad inicial (θ_{il}^{ini}) igual a 0.8, 0.7 y 0.6 respectivamente, en los departamentos adicionales en los que sean entrenados. A su vez, todos los empleados tendrán una productividad inicial, $\theta_{il}^{ini} = 1$, en el departamento en el cual ya están entrenados. Adicionalmente, en este estudio se consideró que la tasa de aprendizaje es constante para cada empleado y departamento, y su valor es $\sigma_{il} = 0.8$. De igual manera, se asumió que el número de repeticiones de trabajo antes del inicio del estudio (*n*) es igual a 1 debido a que los empleados aún no se encuentran entrenados en habilidades adicionales [16]. El factor exponencial b_{il} y la pendiente de la curva del olvido f_{il} no presentan diferencias entre departamentos. Finalmente, para modelar la evolución de la productividad teniendo en cuenta el efecto del aprendizaje y olvido, se consideraron $\xi = 3$ y $n_{eq} = 2$. Todos los valores indicados son típicamente reportados en la literatura.

Datos simulados. Mediante datos históricos se conoce que la demanda en horas (r_{ls}) por departamento *l* y semana *s* sigue una distribución normal. Con el propósito de evaluar el impacto de la variabilidad de la demanda en los resultados de esta metodología, se consideraron tres escenarios de variabilidad; representados mediante los siguientes coeficientes de variación (CV): 10%, 20% y 30%. Luego, para cada CV y siguiendo una distribución de probabilidad normal truncada en cero (para evitar valores negativos), se realizó una simulación de Monte Carlo para obtener los valores de demanda para cada una de las 52 semanas del horizonte de planificación.

5.2 Experimentos y métricas de desempeño

Experimentos. Con el fin de comparar el impacto de la evolución de la productividad en las decisiones de polifuncionalidad, se definieron los siguientes dos experimentos:

1. *Experimento 1*: Los empleados pueden ser entrenados en uno o más departamentos adicionales, pero se modelarán como una fuerza laboral homogénea. Es decir,

todos los empleados tienen una productividad laboral igual 1 en todos los departamentos donde sean entrenados.

2. *Experimento 2*: Los empleados pueden ser entrenados en uno o más departamentos adicionales, pero se modelarán como una fuerza laboral heterogénea. Tal que se incorpora el efecto del fenómeno de aprendizaje y olvido.

Cabe resaltar dos cosas. Primero, el Experimento 2 es equivalente a la metodología propuesta en este artículo. Segundo, para cada experimento, se consideran los tres escenarios de variabilidad en la demanda definidos previamente (CV = 10%, 20% y 30%).

Métricas de desempeño. Con el fin de evaluar el desempeño de las soluciones, se utilizarán dos métricas, las cuales permitirán medir los requerimientos de polifuncionalidad.

1. *Porcentaje de empleados polifuncionales*: calcula el número de empleados polifuncionales requeridos, en relación con el total de empleados en la tienda.

$$\%ME = \frac{N°Empleados_polifuncionales}{|I|}.100 \tag{20}$$

2. *Porcentaje de polifuncionalidad total*: se calcula como el número de habilidades adicionales entrenadas, en relación con el número máximo de habilidades posibles de entrenar.

$$\%TM = \frac{\sum_{i\in I}\sum_{l\in L: l\neq mi} x_{il}}{|I|\left(|L|-1\right)}.100 \tag{21}$$

5.3 Resultados y discusión

La formulación propuesta fue escrita en AMPL y resuelta usando el software ILOG CPLEX 12.9.0. A su vez, se empleó un PC con un procesador Intel (R) Core (TM) i5-7200U CPU @ 2.50 GHz 2.71 GHz. y 4GB de RAM. Para todos los escenarios se llegó a optimalidad en menos de 60 segundos. Además, la Tabla 3 muestra el número de variables y restricciones que se generó en cada uno de los escenarios probados. Note que, como la estructura del problema no cambia de un escenario a otro, el tamaño del modelo es el mismo en todos ellos.

Tabla 3. Características del modelo.

Experimento	%CV	Variables Binarias	Variables Continuas	Restricciones
1	10	150	10 341	10 035
	20	150	10 341	10 035
	30	150	10 341	10 035
2	10	150	10 342	10 036
	20	150	10 342	10 036
	30	150	10 342	10 036

El fenómeno de aprendizaje y olvido tiene un impacto en las decisiones de polifuncionalidad. Por lo cual, a partir de un análisis de costos y las métricas de desempeño %ME

y %TM, se evaluaron y compararon los resultados obtenidos en los Experimentos 1 y 2. Primero, para el Experimento 2, se reportó que la productividad final (θ_{il}^{FP}) obtenida para los tres tipos de empleados (en los departamentos secundarios) fue la siguiente: Senior, 0.9; Estándar, 0.8; y Junior, 0.7. Esto indica que, aquellos modelos que asumen una fuerza laboral homogénea como la descrita en el Experimento 1, pueden entregar soluciones que no se ajustan a la realidad de las empresas.

Continuando con el análisis, la Tabla 4 presenta los resultados obtenidos para cada experimento; de allí se desprenden los siguientes análisis. Primero, y para ambos experimentos, se observa que a medida que aumenta el coeficiente de variación (%CV) aumentan los requerimientos de polifuncionalidad (i.e., %ME y %TM). Este resultado es intuitivo, pues a mayores niveles de incertidumbre en la demanda, una mayor inversión en flexibilidad laboral (i.e., polifuncionalidad) permitirá minimizar el desajuste entre la oferta y la demanda de personal. Segundo, para el Experimento 2, se observa que los niveles de polifuncionalidad requeridos son más altos que en el Experimento 1. Este resultado es interesante, pues indica que la incorporación del fenómeno de aprendizaje y olvido exige mayores niveles de flexibilidad para compensar el hecho que los niveles de productividad finales de los empleados polifuncionales (en los departamentos secundarios) ya no son el máximo, i.e., son menores a 1.

Tercero, se debe destacar que aun cuando dos escenarios tengan el mismo valor de %ME, los %TM no tienen por qué ser iguales. Por ejemplo, para %CV=20, se observa que en ambos experimentos se obtuvo %ME=50; sin embargo, el %TM es mayor en el Experimento 2. Esto significa que en ambos experimentos se requirió el mismo número de empleados polifuncionales, pero en el Experimento 2 los empleados polifuncionales se entrenaron en mayor número de departamentos adicionales. De forma general, los resultados reflejados en Tabla 4 muestran que en el Experimento 2 el número máximo de habilidades adicionales entrenadas en un empleado polifuncional fue ν=4, mientras que para el Experimento 1 este número fue ν=3.

Tabla 4. Resultados obtenidos y medidas de desempeño asociados a los Experimentos 1 y 2.

Exp.	%CV	N° Empleados polifuncionales					%ME	%TM	Costo anual (US$)			
		ν=1	ν=2	ν=3	ν=4	Total			ET	ST	PP	Total
1	10	8	1	-	-	9	30	7	10	57 360	-	57 370
	20	13	2	-	-	15	50	13	19	140 760	-	140 779
	30	14	5	1	-	20	67	18	27	163 320	-	163 347
2	10	5	3	2	1	11	37	14	21	62 124	5	62 150
	20	4	7	4	-	15	50	20	30	151 854	8	151 892
	30	5	6	4	2	17	57	25	37	176 256	10	176 303

De la Tabla 4 también se desprende un cuarto análisis asociado a los costos incurridos en cada experimento y CV. Se observa que en el Experimento 2 hay una mayor inversión en polifuncionalidad y, por lo tanto, los costos de entrenamiento (ET) son mayores. Además, en ambos experimentos, se observa que los costos de subdotación (ST) aumentan a medida que aumenta el CV. Sin embargo, el Experimento 1 registra costos de subdotación inferiores al Experimento 2. Este resultado se produce porque el Experimento 1 asume que los empleados polifuncionales son homogéneos y tienen un nivel de productividad máximo en cada uno de los departamentos entrenados (i.e.,

$\theta_{il}^{SP} = \theta_{il}^{FP} = 1$). Es decir, bajo el Experimento 1 la oferta de horas-hombre está 100% disponible, lo cual no ocurre en el Experimento 2 donde el fenómeno de olvido genera una pérdida de productividad. En consecuencia, el Experimento 2 entrega niveles de polifuncionalidad más ajustados a la realidad y, a su vez, no subestima los costos de subdotación. Finalmente, producto de los mayores costos de entrenamiento (ET), de subdotación (ST), y a la incorporación del costo virtual asociado a la pérdida de productividad (PP) generada por el fenómeno de aprendizaje y olvido, el Experimento 2 siempre reporta un costo total mayor respecto al Experimento 1.

6 Conclusiones

En el presente estudio se propuso un modelo de programación entera mixta para resolver un problema de asignación anual de personal que explícitamente incorpora el fenómeno de aprendizaje y olvido y, también, el uso de personal polifuncional a través del enfoque *k-chaining*. El objetivo fue medir y evaluar el impacto del fenómeno de aprendizaje y olvido en las decisiones de polifuncionalidad. El caso de estudio fue una tienda de retail chilena, para un periodo de planificación de un año, en el cual se evaluaron dos experimentos que enfrentaron tres diferentes niveles de variabilidad en la demanda. El primer experimento no incorporó el fenómeno de aprendizaje y olvido y, a su vez, asumió una fuerza laboral homogénea con productividad máxima. El segundo experimento sí incorporó el fenómeno de aprendizaje y olvido y, por lo tanto, modeló una fuerza laboral heterogénea.

Este caso de estudio arrojó varios resultados de interés. Primero, el Experimento 1 siempre reportó costos menores en comparación al Experimento 2. Esto sucede porque el Experimento 1 subestima los costos de entrenamiento y de subdotación de personal, al asumir (de manera poco probable) que todos los empleados polifuncionales siempre tienen máxima productividad en todos los departamentos adicionales donde fueron entrenados. Por otra parte, el Experimento 2 requirió mayores niveles de polifuncionalidad para compensar la pérdida de productividad ocasionada por el fenómeno del olvido. A su vez, dado que los empleados polifuncionales reportaron productividades finales menores a 1 en los departamentos adicionales donde fueron entrenados, los niveles de subdotación reportados fueron mayores con relación al Experimento 1. Estos resultados son interesantes, pues demuestran la importancia de incorporar el fenómeno de aprendizaje y olvido en las decisiones de polifuncionalidad, lo cual lidera la consecución de soluciones más ajustadas a la realidad.

Adicionalmente, se evidenció que, a mayor variabilidad en la demanda, mayores niveles de polifuncionalidad son requeridos. Sumado a esto, para el Experimento 2, el número de habilidades adicionales entrenadas en un empleado polifuncional tomó un máximo de cuatro, mientras que para el Experimento 1 este máximo fue igual a tres.

Finalmente, para futuras investigaciones, sería interesante agregar los siguientes análisis: (1) incorporar en simultáneo decisiones de contratación de personal, lo cual permitiría ajustarse mejor a escenarios de alta variabilidad en la demanda; (2) considerar explícitamente en la formulación matemática condiciones de demanda estocástica, lo

cual permitiría obtener soluciones robustas y factibles ante cambios en dicho parámetro; y (3) realizar un análisis de sensibilidad sobre los parámetros de costos utilizados, lo cual permitiría explorar cambios en la estructura de solución del problema.

Abstract. This paper addresses a days-off scheduling problem that incorporates multiskilling decisions using a 2-chaining policy. The generated closed-chained multiskilling structures minimize the expected training and over/understaffing costs, while assigning rest days between working days to single-skilled and multiskilled employees. This research provides a suitable methodology for a wide range of industries where the main problem is to meet the demand requirements the seven days of the week, but where the employees cannot work daily. The methodology is structured in two steps. First, we develop a deterministic mixed integer linear programming model. Second, the deterministic model is reformulated as a two-stage stochastic optimization model in order to explicitly incorporate demand uncertainty. Our methodology was applied in a case study associated to a Chilean retail store. We use real data but also simulated data to represent various demand variability scenarios. Results showed that the model was able to do the days-off scheduling decisions cost-effectively for a planning horizon of two weeks. Additionally, it was found that the levels of understaffing and overstaffing can vary between weekdays (Monday to Friday) and weekend. Finally, we also observed that the 2-chaining policy was cost-effective in all scenarios; however, when there are very high levels of demand variability, it can be interesting to explore k-chaining with $k \geq 2$ and/or to hire more employees.

Keywords: Multiskilling, Chaining, Days-off scheduling, Workforce flexibility, Retail services.

1 Introduction

The service sector currently contributes more than 60% of production and employment in the world and has a share in international trade of approximately 20% [1], so their systems should be optimized and highly studied. One of the processes with the greatest impact on a service organization is the personnel scheduling. However, in this sector is complex to establish effective personnel scheduling systems that ensure an adequate

customer service level (CSL) and make a most efficient use of resources due to the high level of uncertain demand and unscheduled staff absenteeism. These phenomena produce periods of over- and under-staffing (i.e., staffing levels that are higher or lower than required, respectively) that can directly lead to an increase labor costs and, in turn, deteriorate the customer service levels [2 , 3 , 4].

A source of labor flexibility, supported by the literature, that seeks to counteract the effects of staff shortage/surplus in a service company is to incorporate multiskilled employees who can work on multiple task types (or store departments) [2 , 5],. In addition, chaining is a cost-effective policy that allows to transfer available multiskilled employees from overstaffed departments to understaffed departments. In this policy, a certain number of employees are trained to work in two or more departments, such that these allocation decisions are configured through a bipartite graph that involves different chains types. Particularly, the 2-chaining policy is based on the fact that certain employees are trained to work in a maximum of two departments. This policy has been shown to be one of the most cost-effective and recommended in the literature, because it does not lead to the over-training of the employees and optimizes the multiskilling approach [6].

Also, as mentioned above, the uncertainty in the staff demand is a relevant phenomenon in the context of the personnel scheduling problem in the service companies. Thus, to make decisions under uncertain demand, is useful to apply a two-stage stochastic optimization (TSSO) model that explicitly considers such uncertainty.

Given the above, the intended contribution of this paper to the personnel scheduling problem in the service sector is a model that determines the multiskilling levels that minimize the expected costs associated with training and over/understaffing. The proposed methodology is structured in two steps. First, a days-off scheduling problem is initially formulated as a deterministic mixed integer linear programming model (MILPM), which assigns rest days between working days to single-skilled and multiskilled employees over a two-week planning horizon. Note that, since 2-chaining policies have shown to be very effective in terms of providing flexibility to address uncertain demands, the training plan for employees will be structured through closed chains. Second, the MILPM is reformulated as a TSSO model in order to explicitly incorporate demand uncertainty. Then, our methodology is applied to a case study of a Chilean retail store using commercial software. The performance of the optimization approach is assessed for various demand variability scenarios in order to measure the benefits of the closed-chain multiskilling structures to face uncertainty.

2 Literature Review

There is a wide range of authors who proposed different mathematical models to solve the personnel scheduling problems. Table 1 characterizes a series of articles published in recent decades to obtain an accurate contextualization of the state of the art. The studies are described by the following characteristics:

i) *Personnel scheduling problem* (PSP): based on the classification made by Henao et. al [7], we indicate the type of problem addressed in each study. May be: (a) staffing

(S); (b) shift scheduling (SS); (c) days-off scheduling (DOS); (d) tour scheduling (TS); or (e) assignment (A).

ii) *Multiskilling* (MS): this criterion indicates whether the multiskilling was modeled through a parameter (Par), i.e. as model input, or a decision variable (Var).

iii) *Chaining* (CH): according to the classification presented in Henao et al. [7], the chain types used in each study are indicated. These could be: (a) closed long chain (CLC), one multiskilled employee per task type forming one chain that connects all task types; (b) closed short chain (CSC), a subset of multiskilled employees that connects just a subset of task types; (c) open chain (OC), a long chain which it was not closed; and (d) all-for-one (AxO), where all multiskilled employees are trained for assignment to a single task type.

iv) *Workforce type* (WFT): May be: (a) homogeneous workforce (HO), which means that the productivity of an employee does not change if he or she is assigned different task types; and (b) heterogeneous workforce (HT), which means that, if employees increase the number of task types they are able to work, then productivity can decrease.

v) *Uncertainty* (U): Indicates whether or not the problem posed by study considers: (a) demand uncertainty (D); and/or (b) supply variability (O) (i.e., unscheduled staff absenteeism).

vi) *Methods* (ME): Indicates the solution method used. May be: (a) simulation (S); (b) heuristics (H); (c) traditional optimization (OPT); (d) analytic (AN); and (e) metaheuristics (M).

vii) *Uncertainty modeling approach* (UMA): Indicates the modeling approach that was used to explicitly incorporates uncertainty into an optimization model. May be: (a) two-stage stochastic optimization (TSSO); (b) robust optimization (RO); and (c) closed-form equation (CF).

viii) *Application (AP):* We have found different fields in which the authors do their research, such as hospitals (H), retail (R), airports (AI), cyber security (CS), services (S), and manufacturing (MA).

Table 1 shows that multiskilling is a source of labor flexibility very used to address the personnel scheduling problems. Complementing it with chaining undoubtedly has a high impact to minimize the levels of over/understaffing. However, even though the chaining represents a growing trend according to the state of the art, there is still a need for more work to prove its effectiveness. On the other hand, the authors focus on shift scheduling or tour scheduling, so days-off scheduling represents a gap in the literature. This represents a field of interest, since days-off scheduling is a need in a wide range of industries where the main problem is to meet the demand requirements the seven days of the week, but where the employees cannot work daily. Examples include restaurants, power plants, hospitals, and retail stores. In addition, few studies explicitly incorporated the demand uncertainty into the mathematical formulation.

The contribution of this work is twofold. First, we evaluate the impact of closed-chained multiskilling structures on days-off scheduling in the service sector, particularly for the retail industry. Second, we propose a TSSO approach to make the uncertain demand explicit. It is important to note that our modeling will consider multiskilling as

a decision variable, thus, the model will decide how many employees will be multi-skilled and in which store departments, while at the same time will produce a set of closed chains. This will allow to consider a much wider range of assignment possibilities and providing a much more efficient way to satisfy the staff demand.

3 Problem description

The problem we propose to study consists in generating a training plan for a retail store, and then, obtaining a schedule of resting and working days for each them over a two-week planning horizon. It is assumed that each department has hired a set of employees initially single-skilled and therefore trained to work in a single department. In more specific terms, our problem will be to solve a biweekly DOS that simultaneously decides how many single-skilled employees should be multiskilled, in which second department to form closed-chained multiskilling structures, and how to assign working and resting days to each employee. In addition, each employee can work maximum five consecutive days and must work a given number of weekly hours as specified by his/her contract. The objective is to minimize the expected costs associated with training and over/understaffing. Table 2 shows the notation used in the formulation of the problem.

Table 2. Sets, parameters, and variables of the days-of scheduling problem.

Sets	
I	Store employees, indexed by i
L	Store departments, indexed by l
I_l	Employees under contract in department l, indexed by i, $\forall\, l \in L$
S	Set of weeks, indexed by s
D	Days of the biweekly planning horizon, indexed by d, $\{M1, Tu1, W1, Th1, F1, S1, Su1, M2, Tu2, W2, Th2, F2, S2, Su2\}$
D_s	Set of days of the week s
$D5_d$	Set of consecutive days after the day d
D^+	Set of maximum consecutive days, indexed by d, $\{M1, Tu1, W1, Th1, F1, S1, Su1, M2, Tu2\}$
Parameters	
r_{ld}	Number of daily hours demanded in department l on day d, $\forall l \in L, d \in D$
h	Number of weekly hours an employee must work according to his/her contract
t	Number of working hours an employee must work per day
m_i	Department for which employee i was initially trained, $\forall i \in I$
μ	Staff shortage cost per hour (equivalent to the expected cost of lost sales)
o	Staff surplus cost per hour (equivalent to the opportunity cost of idle employee-hours)
c	Training cost of an employee to work in any department
Variables	
x_{il}	Equal to 1 if employee *i* is trained for department *l*, otherwise 0, $\forall i \in I, l \in L$
v_i	Equal to 1 if employee *i* is multiskilled, otherwise 0, $\forall i \in I$
ω_{ild}	Number of working hours assigned to employee i in department l in day $d, \forall i \in I, l \in L, d \in D$
y_{id}	Equal to 1 if employee i works in day d, otherwise 0, $\forall i \in I, d \in D$
k_{ld}	Staff shortage in hours in department l on day d, $\forall l \in L, d \in D$
δ_{ld}	Staff surplus in hours in department l in day $d, \forall l \in L, d \in D$
z_i	Equal to 1 if employee *i* has days off in the first weekend (S1, Su1), and equal to 0 if employee has days off in the second weekend (S2, Su2), $\forall i \in I$

Our formulation incorporates the following assumptions: (1) Employees can be trained in a maximum of two store departments. (2) Employees have the same level of productivity for each department (i.e., homogeneous workforce). (3) Employees may work a maximum of five consecutive days. (4) The planning horizon has 14-days (two weeks). (5) All employees must work exactly five days per week with 9-hour work shifts per working day. (6) Unscheduled staff absenteeism is not considered. (7) The daily hours demand in each department is a random parameter. (8) All employees are initially trained in single department. (9) The cost of staff shortage is the same for all departments, which is a common assumption on the field. (10) The cost of staff surplus is an

opportunity cost for idle staff, and it is also equal for all departments. (11) Training costs are equal for each department.

4 Methodology

In this section we present a deterministic version of our mixed integer linear programming model for solving the days-off scheduling problem with chaining as just described above. Later, we will introduce the necessary modifications to transform the model into a two-stage stochastic formulation incorporating demand uncertainty for solving the same problem.

4.1 Deterministic model

The deterministic model can now be formulated as follows:

$$Min \quad \sum_{i\in I}\sum_{l\in L: l\neq m_i} cx_{il} + \sum_{d\in D}\sum_{l\in L}(\mu k_{ld} + o\delta_{ld}) \tag{1}$$

s.t.

$$\sum_{i\in I}\omega_{ild} + k_{ld} - \delta_{ld} = r_{ld} \qquad \forall l \in L, d \in D \tag{2}$$
$$\omega_{ild} \leq t x_{il} \qquad \forall i \in I, l \in L, d \in D \tag{3}$$
$$\sum_{l\in L}\omega_{ild} = t y_{id} \qquad \forall i \in I, d \in D \tag{4}$$
$$\sum_{d\in D_S} y_{id} = 5 \qquad \forall i \in I, s \in S \tag{5}$$
$$y_{id} + \sum_{\overline{d}\in D5_d} y_{i\overline{d}} \leq 5 \qquad \forall i \in I, d \in D^{+} \tag{6}$$
$$y_{id} \leq 1 - z_i \qquad \forall i \in I, d \in D\{S1, Su1\} \tag{7}$$
$$y_{id} \leq z_i \qquad \forall i \in I, d \in D\{S2, Su2\} \tag{8}$$
$$x_{il} = 1 \qquad \forall i \in I, l \in L: l = m_i \tag{9}$$
$$v_i = \sum_{l\in L: l\neq m_i} x_{il} \qquad \forall i \in I \tag{10}$$
$$v_i \leq 1 \qquad \forall i \in I \tag{11}$$
$$\sum_{i\in I_l} v_i = \sum_{i\in\{I-I_l\}} x_{il} \qquad \forall l \in L \tag{12}$$
$$y_{id} \in \{0,1\} \qquad \forall i \in I, d \in D \tag{13}$$
$$x_{il} \in \{0,1\} \qquad \forall i \in I, l \in L \tag{14}$$
$$z_i \in \{0,1\} \qquad \forall i \in I \tag{15}$$
$$\omega_{ild} \geq 0 \qquad \forall i \in I, l \in L, d \in D \tag{16}$$
$$k_{ld} \geq 0 \qquad \forall l \in L, d \in D \tag{17}$$
$$\delta_{ld} \geq 0 \qquad \forall l \in L, d \in D \tag{18}$$
$$v_i \geq 0 \qquad \forall i \in I \tag{19}$$

In this formulation the objective function (1) minimizes the following three biweekly costs: personnel training, staff shortage, and staff surplus. Constraints (2) along with the constraints (17) and (18) yield the levels of staff shortage/surplus associated with each department. Constraints (3) ensure that individual employees be assigned to work in, and only in, departments they have been trained for. Constraints (4) ensure that employees work exactly the number of hours required in each working day. Constraints from (5) to (8) implement days off scheduling constraints developed by Altner et al. [21]. Constraints (5) indicate that each employee must work five days per week. Note

that, constraints (4) and (5) ensure that employees work exactly the weekly number of hours required by the employment contract, i.e., h. Constraints (6) indicate that each employee can work a maximum of 5 consecutive days. Constraints (7) and (8) ensure that each employee has at least one weekend off. Constraints (9) determine the department each employee was originally trained for. Constraints (10) determine whether an employee is multiskilled or single-skilled. Constraints (11) ensure that an employee is trained in a maximum of two departments. Constraints (12) indicate that the number of employees who have been trained in the department *l* (from other departments) should be equal to the number of multiskilled employees belonging to the department *l*. Constraints (11) and (12) ensure that employees are assigned to closed-chained multiskilling structures. Finally, constraints (13)-(19) define the domain of each problem variable.

4.2 Two-stage stochastic optimization model

The two-stage stochastic optimization model (TSSO) arises when full knowledge about the distribution of uncertain demand is available and is defined with two variable types: first stage and second-stage. The first-stage variables are related to decisions that are made before the realization of the uncertain parameters become available, that is, decisions such as the training of employees in a second department. The second-stage variables are related to decisions that are made after the realization of daily demand is known, that is, decisions such as personnel assignment to minimize the levels of over/under-staffing. The second-stage variables depend on the first-stage variables and the uncertain parameter.

To solve this problem the sample average approximation (SAA) approach will be implemented. This approach creates one set of second-stage variables for every possible scenario of demand. The quality of the SAA is related to how large is the set of samples. The set of scenarios comes from the continuous distribution of the random parameters ξ represented by $\xi \in \Xi$, where Ξ is the set of scenarios generated, which forms the SAA problem. Below, we present the TSSO version of the deterministic formulation (1)-(19), written as follows:

$$Min \quad \sum_{i\in I}\sum_{l\in L:l\neq m_i} cx_{il} + \frac{1}{|\Xi|}\left[\sum_{\xi\in\Xi}\sum_{d\in D}\sum_{l\in L}\mu k_{ld}(\xi) + o\delta_{ld}(\xi)\right] \tag{20}$$

s.t.

$$\sum_{i\in I}\omega_{ild}(\xi) + k_{ld}(\xi) - \delta_{ld}(\xi) = r_{ld}(\xi) \qquad \forall l \in L, d \in D, \xi \in \Xi \tag{21}$$

$$\omega_{ild}(\xi) \leq tx_{il} \qquad \forall i \in I, l \in L, d \in D, \xi \in \Xi \tag{22}$$

$$\sum_{l\in L}\omega_{ild}(\xi) = ty_{id} \qquad \forall i \in I, d \in D, \xi \in \Xi \tag{23}$$

$$\sum_{d\in D_S} y_{id} = 5 \qquad \forall i \in I, s \in S \tag{24}$$

$$y_{id} + \sum_{\overline{d}\in D5_d} y_{i\overline{d}} \leq 5 \qquad \forall i \in I, d \in D^+ \tag{25}$$

$$y_{id} \leq 1 - z_i \qquad \forall i \in I, d \in D\{S1, Su1\} \tag{26}$$

$$y_{id} \leq z_i \qquad \forall i \in I, d \in D\{S2, Su2\} \tag{27}$$

$$x_{il} = 1 \qquad \forall i \in I, l \in L: l = m_i \tag{28}$$

$$v_i = \sum_{l\in L:l\neq m_i} x_{il} \qquad \forall i \in I \tag{29}$$

$$v_i \leq 1 \qquad \forall i \in I \tag{30}$$

$$\sum_{i\in I_l} v_i = \sum_{i\in\{I-I_l\}} x_{il} \quad \forall l \in L \tag{31}$$
$$y_{id} \in \{0,1\} \quad \forall i \in I, d \in D \tag{32}$$
$$x_{il} \in \{0,1\} \quad \forall i \in I, l \in L \tag{33}$$
$$z_i \in \{0,1\} \quad \forall i \in I \tag{34}$$
$$\omega_{ild}(\xi) \geq 0 \quad \forall i \in I, l \in L, d \in D, \xi \in \Xi \tag{35}$$
$$k_{ld}(\xi) \geq 0 \quad \forall l \in L, d \in D, \xi \in \Xi \tag{36}$$
$$\delta_{ld}(\xi) \geq 0 \quad \forall l \in L, d \in D, \xi \in \Xi \tag{37}$$
$$v_i \geq 0 \quad \forall i \in I \tag{38}$$

The objective function (20) aims to minimize the training cost (first-stage decisions) and the expected biweekly cost of staff shortages and surpluses (second-stage decisions). In this TSSO model the decision about which employees will be multiskilled is done in the first stage and this will affect the levels of staff shortage/surplus in the second stage. The main objective in the TSSO is to choose the first-stage variables in order to minimize the sum of first stage costs and the expected value of the random second stage costs. Constraints (21)-(38) are accordingly extended from (2)-(19) to consider the uncertainty demand and scenario-dependent second stage variables.

5 Case study, results, and discussion

This section presents the case study used to validate our methodology, as well as its computational implementation.

5.1 Case study

The case study is based on real and simulated data, which is derived from a retail store in Chile. This retail store currently has employees hired in specific departments. Each department currently constitutes a store business unit and at that level is where the store's training and employee scheduling decisions are made.

The real data corresponds to the information related to the store size, the number of departments, the number of employees hired in each department, employment-contract characteristics, mean values on the daily demand in each department, as well as costs related to the model. Regarding the simulated data, these include information about the random parameter of daily hours demand in each store department, which corresponds to the uncertain parameter in our model. The following is a detailed description of the data.

Real data. The case study considers a retail store with 6 departments and 30 employees, that is, $|L| = 6$ and $|I| = 30$. The employment contract stipulates that an employee must comply with 45 hours per week ($h = 45$) and 9 hours per working day ($t = 9$). Regarding the cost parameters, there is a minimal training cost value per employee ($c = US\$1\ biweek/employee$), which has been estimated according to Henao et al. [7 , 15 , 22]. This minimal training cost allows interpreting the results as an upper bound on the potential contribution of multiskilling to store performance [2 , 23]. Finally, the

costs related to under/over-staffing are estimated on an hourly basis and are $u = US\$60/h$ and $s = US\$15/h$, respectively.

Simulated data. Since the TSSO model (20)-(38) is solved by a SAA method, this implies that we use a Monte Carlo simulation to randomly generate 60 scenarios for the parameters of daily hours demand in each department $r_{l_d}(\xi), \forall l \in L, \forall d \in D, \xi \in \Xi$ such that $\Xi = 60$. We consider that the probability density function (pdf) for the demand of each department follows a normal distribution and it is zero-truncated to prevent generating negative demand values. Finally, in the simulation Monte Carlo, we consider three representative variability levels for demand in a department: coefficient of variation $CV = 10\%, 30\%, 50\%$.

5.2 Results and discussion

This section presents the results of the TSSO model presented in Section 4.2 according to the conditions presented in the case study described in Section 5.1. The model was coded in AMPL and solved using the commercial software CPLEX 12.9.0 running through NEOS-server for 8 h (restrictive). Considering the running conditions, we obtained optimality gaps of less than 0.3%.

The results and discussion of our methodology are divided into the following three subsections: models' size and computational times; multiskilling results; and days-off scheduling results. The last two subsections only present results associated with the TSSO model.

Model's size and computational times. As it was mentioned before, the run time of the TSSO model was restricted to 8 hours. Thus, for each coefficient of variation of the staff demand (*CV* = 10%, 30% and 50%) the same computational time was maintained. Regarding the deterministic model, the running time was of approximately 14.3 seconds for each CV. Table 3 presents the differences in model size between the deterministic model (DT) and the associated TSSO model.

Table 3. Comparison between the deterministic and stochastic models.

Element	TSSO	DT
Constraints	156 738	3 102
Binary variables	600	600
Continuous variables	161 322	2 730

Multiskilling results. The purpose of this subsection is to evaluate the multiskilling requirements associated with each CV. Thus, for each CV, these requirements were measured through three metrics and are presented in Table 4. First, we present the number of multiskilled employees required in each store department. Second, we calculate the percentage of multiskilled employees (*%ME*), which represents the number of multiskilled employees required, in relation to the total number of hired employees. Third,

the percentage of total multiskilling (*%TM*) is calculated, representing the number of additional skills trained, in relation to the theoretical maximum number feasible (at the store level).

Table 4. Multiskilling results and metrics with different demand uncertainty levels.

	Store department							
	1	2	3	4	5	6		
%CV	**No. multiskilled employees**						***%ME***	***%TM***
10	3	2	2	2	2	3	47	9
30	5	5	2	3	3	5	77	15
50	7	5	3	3	4	8	100	20

We observed that the number of multiskilled employees per store department, %ME, and %TM increase as the %CV of demand increases. This result is intuitive because the greater the variability in demand, there will be greater opportunities to transfer multiskilled employees from overstaffed departments to understaffed departments.

In detail, when demand variability is the lowest (i.e., CV=10%), the %ME is almost equal to 50%. In turn, when demand variability is equal to 30%, the %ME is equal to 77%. Finally, when demand variability is the highest (i.e., CV=50%), the optimal number of multiskilled employees per department is equal to its total staff, i.e., ME=100%. This result is interesting since it indicates that when there are very high levels of demand variability, a 2-chaining policy cannot be sufficient to minimize the costs of over/understaffing. That is, it can be interesting to evaluate two new strategies: (1) to explore *k*-chaining policies where certain employees can be trained to work in two or more departments [24]; and (2) to hire more employees.

Days-off scheduling results. For the second week of our planning horizon and each CV in the demand, Figure 1 shows a comparison between the number of employees assigned and the over/understaffing hours in each store department. A plot of the first week, not shown in the figure, would indicate the same general tendency. Figure 1 shows that those days where there is more staff demand (i.e., weekend), a greater number of employees are assigned.

In detail, when $CV = 10\%$, we observed that from Monday to Friday, less employees are assigned in comparison to the weekend; this is reasonable given that on Saturday and Sunday there are higher personnel requirements. But as *CV* increases, the number of employees assigned to weekdays (Monday to Friday) versus weekends become similar. This result is not surprising, since at higher levels of variability in demand, the model decides to assign almost the same amount of staff every day, which is a conservative decision. In addition, this makes sense since the over/understaffing costs do not vary according to the day of the week.

Regarding of the demand satisfaction, Figure 1 shows that as CV increases, the levels of over/understaffing are also greater. This is also a predictable behavior, since, if there is greater demand uncertainty, it is more difficult to adjust the staff supply to the staff demand. Finally, the high levels of staff shortage during the weekend suggest that it is

convenient to hire more employees and/or to allow multiskilled employees to be trained in more than one additional department.

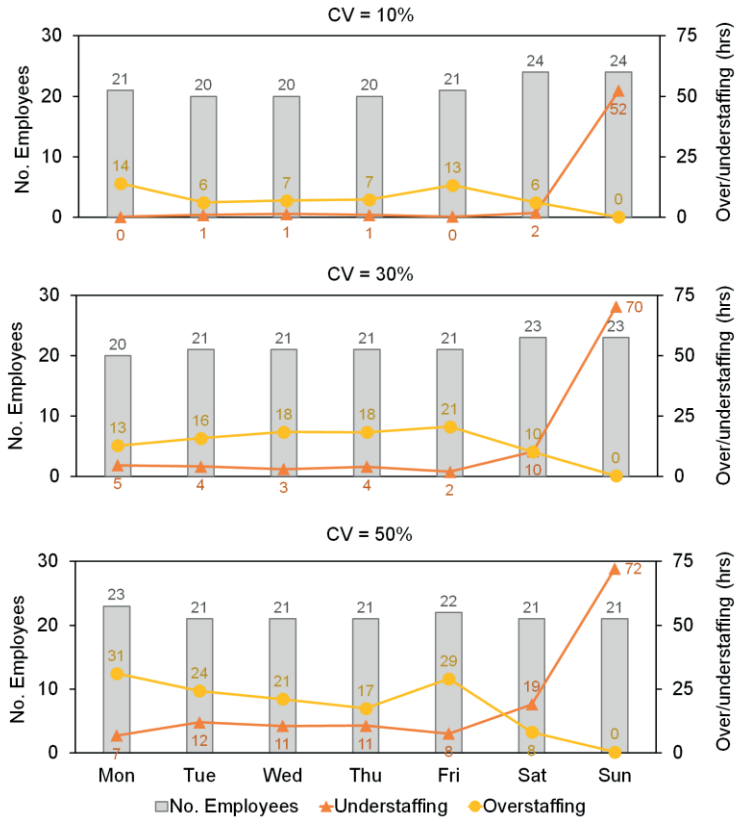

Fig. 1. Comparison between the number of employees assigned and the over/understaffing hours in each department for different levels of uncertainty in the demand.

6 Conclusions

This research presents a new methodology to determine the multiskilling levels that minimize the expected costs associated with training and over/understaffing. In a novel way we ensure the training plans using the approach 2-chaining. The problem consists in assigs to rest days between working days to single-skilled and multiskilled employees over a two-week planning horizon. The proposed methodology initially formulates a deterministic mixed integer linear programming model, and secondly, presents a stochastic version of the model (TSSO). The TSSO model is validated through a case study associated to a Chilean retail store. The performance of the TSSO model is assessed for various demand variability scenarios in order to measure the benefits of the closed-chain multiskilling structures to face uncertainty.

Regarding the results associated with the model's size and its computational times, it was found that the stochastic version of the model led to an increase in the computational times. However, the TSSO times are acceptable since personnel training decisions are tactical-strategic and, thus, made in medium and long-term planning horizons.

Regarding the results associated with the multiskilling requirements, we observe an intuitive result, since the required number of multiskilled employees grows with the demand coefficient of variation. In addition, we found that when there are very high levels of demand variability, it can be interesting to explore *k*-chaining policies where certain employees can be trained to work in two or more departments.

Regarding the results associated with the days-off scheduling problem, we observe (as expected) that those days with the highest demand also have a greater number of assigned employees. Thus, there is a greater staff supply on weekends. In addition, we can also observe that when there are very high levels of demand variability, increases in multiskilling are not enough, since increases in capacity are also required to minimize the levels of staff shortage. That is, it is necessary to hire more employees.

As regards future research, we think it would be valuable to include into the model staffing decisions, where the amount of personnel to be hired is decided. Also, it can be interesting to evaluate *k*-chaining policies where certain employees are trained to work in *k* departments with $k \geq 2$. Finally, the TSSO model could also explicitly incorporate the uncertainty in the staff supply, that is, unscheduled staff absenteeism.

Beneficios de la polifuncionalidad laboral en la industria retail: Enfoque "k-chaining" con incertidumbre en la demanda

Yessica Mercado Morales[1] y César Augusto Henao[1][0000-0001-8253-5794]

cahenao@uninorte.edu.co

Resumen En la industria retail, la estacionalidad de la demanda, su incertidumbre, y el ausentismo no programado de personal producen un desajuste entre la oferta y la demanda, que puede aumentar considerablemente los costos de sobredotación y subdotación de personal. El uso de personal polifuncional es una fuente de flexibilidad atractiva para minimizar tal descalce. Este trabajo presenta un modelo de programación lineal entera mixta para estructurar las habilidades polifuncionales de un conjunto de empleados. Para incorporar explícitamente la incertidumbre de la demanda desarrollamos un enfoque de optimización estocástica en dos etapas. Posteriormente, mediante simulación Montecarlo se analiza el desempeño de las soluciones para distintos niveles de variabilidad en la demanda. Para probar el rendimiento del enfoque estocástico propuesto, este se compara con las soluciones de dos enfoques miopes: polifuncionalidad cero y polifuncionalidad total. La metodología propuesta es aplicada a un caso de estudio en una tienda de retail chilena, usando datos reales y simulados. Nuestros resultados mostraron que el enfoque propuesto reportó el máximo beneficio posible para todos los niveles de variabilidad. Finalmente, brindamos información a los responsables de la toma de decisiones para abordar dos aspectos claves de la polifuncionalidad: cuánto agregar y cómo se debe agregar.

Palabras claves: Polifuncionalidad, Chaining, Programación de personal, Programación estocástica, Retail.

1 Introducción

El sector servicios, y en particular la industria de retail, deben responder no solo ante fenómenos predecibles como la estacionalidad de la demanda sino también ante fenómenos impredecibles como su incertidumbre y el ausentismo no programado de personal. Ambos fenómenos complican la planificación eficiente de los recursos humanos (RRHH), pues dificultan el ajuste entre la oferta y la demanda de personal. Por lo que incluso empresas con un sistema efectivo de programación de turnos de trabajo pueden enfrentar problemas de sobredotación y subdotación de personal en varios momentos durante el curso de una semana [1, 2, 3, 4]. La literatura en esta área sugiere que varios autores han abordado efectivamente los problemas de sobredotación y subdotación usando personal polifuncional.

En una tienda retail, el personal polifuncional es uno que tiene la habilidad para trabajar en *k* departamentos (con $k \geq 2$), lo cual permite al gerente operacional transferir empleados polifuncionales de departamentos con sobredotación de personal a aquellos con presencia de subdotación. Muchos investigadores han encontrado que el *k-chaining* es la política más costo-efectiva para estructurar una fuerza laboral polifuncional [2, 3, 5, 6, 7, 8]. Específicamente el *k-chaining* implica que ciertos empleados estén capacitados para trabajar en *k* departamentos con $k \geq 2$ y que estas decisiones de asignación de empleados y departamentos se configuran a través de un grafo bipartito que involucra cadenas largas cerradas (CLC) y/o cadenas cortas cerradas (CCC). En una CLC hay un empleado polifuncional por departamento formando una única cadena que conecta todos los departamentos de la tienda, mientras que en una CCC hay un subconjunto de empleados polifuncionales que conecta un subconjunto de departamentos. Particularmente, la política *2-chaining* ha sido reportada como la política más popular y recomendada en la literatura [2, 3, 7, 8, 9]. Bajo esta política todos los empleados polifuncionales están entrenados en máximo dos departamentos, es decir, $k=2$ (ver Figura 1).

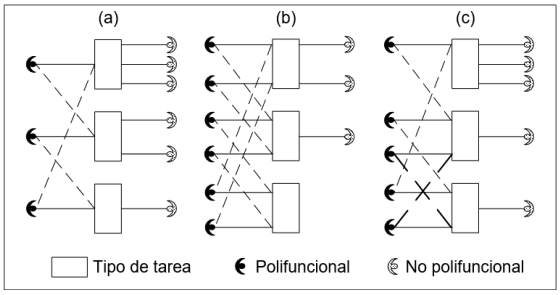

Figura 1. Configuraciones *2-chaining*: (a) Una CLC; (b) Dos CLC idénticas; y (c) Una CLC y Una CCC. Fuente: Henao et al. [2].

Pocos estudios han explorado los beneficios de la implementación de *políticas k-chaining* con $k \geq 2$. La Figura 2 muestra ejemplos de configuraciones de este tipo. En Wang y Zhang [10] los autores evaluaron y compararon el rendimiento de CLCs usando una política *2-chaining* versus una política *k-chaining* con $k>2$. Ellos encontraron que, a mayores niveles de variación en la demanda, las políticas *k-chaining* con $k>2$ conservaron altos niveles de rendimiento a diferencia de las políticas *2-chainnig*. Esto sugiere que ante altos niveles de incertidumbre en la demanda es más beneficioso tener un mayor grado de flexibilidad en el encadenamiento. A su vez, sus resultados también mostraron que hay rendimientos decrecientes a escala a medida que *k* aumenta, es decir, los rendimientos cuando $k=5$ y $k=6$ son casi idénticos. Por lo tanto, niveles de polifuncionalidad muy altos pueden ser imprácticos e innecesarios, y, en consecuencia, también se requiere establecer políticas claras que permitan definir los niveles de polifuncionalidad más costo-efectivos.

En este trabajo se propone una metodología novedosa para evaluar los beneficios del encadenamiento con incertidumbre en la demanda. Primero, el problema se formula como un Modelo de Programación Lineal Entera Mixta (MPLEM) determinístico. Nuestra formulación se diferencia de estudios previos en la literatura puesto que se definen estructuras de polifuncionalidad a través de políticas *k-chaining* con $k \geq 2$ garantizando la formación de cadenas cerradas (CLC y/o CCC). Segundo el MPLEM se

reformula en un modelo de optimización estocástica de dos etapas (TSSO, por sus siglas en ingles) para incorporar la incertidumbre de la demanda. Finalmente, se aplica la metodología propuesta para un caso de estudio en una tienda de retail chilena, considerando distintos niveles de variabilidad en la demanda.

2 Revisión de literatura

La Tabla 1 presenta una revisión de estudios consultados que han tratado el problema de polifuncionalidad en la planificación de los RRHH. A continuación, se definen los elementos presentes en la Tabla 1:

1. *Nivel de decisión de los RRHH* (ND): Indica el tipo de problema de programación de personal abordado en cada estudio. Puede ser: (a) dotación de personal (D); (b) asignación de turnos diarios (AT); (c) asignación de días de descanso (ADD), (c) programación semanal de turnos (PST), donde los días de descanso y turnos de trabajo son asignados simultáneamente; y (d) asignación (A). Este último problema se refiere al problema de asignación de personal, el cual es abordado en nuestro estudio.
2. *Polifuncionalidad* (PF): Indica si la polifuncionalidad fue modelada cómo un parámetro (Par), o una variable de decisión (Var).
3. *Incertidumbre en la demanda* (ID): Indica sí el problema consideró variabilidad en la demanda.
4. *Incertidumbre en la oferta* (IO): Indica sí el problema consideró variabilidad en la oferta (es decir, ausentismo no programado de personal).
5. *Encadenamiento* (*Chaining*)*:* Indica si el estudio usó una política estricta de *2-chaining* o si usó una política *k-chaining* con $k \geq 2$. También se indica si el estudio no consideró ninguna de las dos políticas.
6. *Número de habilidades* (H): Indica si en el estudio existe una restricción para limitar el número máximo de habilidades en los empleados polifuncionales. El estudio puede ser: (a) *restringido* (R), cada empleado polifuncional puede tener solo dos habilidades y (b) *no restringido* (NR), la cantidad de habilidades no está restringida, es decir, cada empleado polifuncional puede tener más de dos habilidades en total.

7. *Método* (M)*:* Indica el método de solución usado. Pueden ser: (a) heurísticas (H); (b) simulación (S); (c) optimización (OPT); y (d) analítica (AN); y (e) Procesos de Markov (MP).
8. *Modelación de la incertidumbre* (MI): Indica el enfoque que se utilizó para evaluar la incertidumbre asociada a los parámetros de un modelo. (1) *In-optimización*: enfoques que incorporan la incertidumbre explícitamente en la formulación matemática, pueden ser: (a) ecuación cerrada (EC); (b) programación estocástica (PE); (c) optimización robusta (OR); y (d) optimización distributiva robusta (ODR). (2) *Post-optimización*: enfoques que evalúan el impacto de la incertidumbre una vez se tiene la solución determinística del problema, pueden ser: (a) análisis de sensibilidad (AS); y (b) evaluación de múltiples escenarios (EME).
9. *Aplicación* (AP): Indica el sector o industria de aplicación del estudio. Pueden ser: (a) Envío de carga (CA); (b) Manufactura (MA); (c) Central eléctrica (CE); (d) Centros de llamadas (CL); (e) Tecnología (TE); (f) Salud (SA); y (g) Retail (RE).

2.1. Principales vacíos encontrados

En la extensa literatura sobre polifuncionalidad laboral es posible identificar los siguientes vacíos.

Primero, la Tabla 1 muestra que a pesar de que existen múltiples artículos que estudian la polifuncionalidad, la mayoría de ellos incorporan la polifuncionalidad como un dato de entrada y no como una variable que indique si un empleado será entrenado en un determinado conjunto de habilidades o no. Esto tiene el efecto negativo de restringir las consideraciones de diseño y limitar las posibilidades de encontrar mejores soluciones. Del mismo modo, también se muestra que hay estudios que evalúan los beneficios de la polifuncionalidad mediante el enfoque *chaining* ($k=2$ o $k\geq2$). Sin embargo, solo algunos de estos estudios incorporan la polifuncionalidad como una variable de decisión con el propósito de desarrollar políticas de *k-chaining* [2, 3, 5, 8, 9, 10, 14, 21, 22].

Segundo, la Tabla 1 también muestra que hay varios estudios que evalúan los beneficios de la polifuncionalidad ante incertidumbre, ya sea en la demanda o en la oferta. Sin embargo, solo [2, 3, 7, 10, 22, 24] incorporaron explícitamente esta incertidumbre dentro de la formulación matemática (es decir, enfoque *in*-optimización). Por lo tanto, las soluciones obtenidas en tales trabajos se consideran buenas y robustas ante distintos niveles de incertidumbre. No pasa esto con los estudios que evaluaron la incertidumbre usando un enfoque *post*-optimización, pues tales trabajos no pueden garantizar robustez o factibilidad de la solución determinística encontrada ante presencia de incertidumbre.

Tercero, se observa en la Tabla 1 que la mayoría de los estudios que consideran el enfoque *chaining* restringen el número de habilidades de los empleados polifuncionales a un máximo de dos. Además, a excepción de Wallace y Whitt [5] e Iravani et al. [6] cuyos estudios se aplican en *call centers*, los estudios que implementan *k-chaining* con $k\geq2$ se focalizan principalmente en el sector manufactura. Se debe destacar que, a diferencia del sector manufactura donde el problema de asignación de recursos se formula típicamente como un sistema balanceado (igual número de nodos de oferta y de demanda), en la industria retail el problema de asignación es de naturaleza desbalanceado (mayor número de nodos de oferta (empleados) que nodos de demanda (departamentos)). Por lo cual, el enfoque *k-chaining* en retail exige nuevos desafíos metodológicos.

En resumen, la exhaustiva revisión de literatura muestra que para la industria retail no hay estudios que en simultáneo evalúen los potenciales beneficios de usar políticas *k-chaining* con $k\geq2$, que modelen la polifuncionalidad como una variable de decisión, y que también incorporen explícitamente dentro la formulación matemática la incertidumbre de la demanda. Este trabajo abordará en simultáneo todos los vacíos listados.

3 Descripción del problema

El problema que se propone estudiar en este trabajo consiste en planificar una fuerza laboral polifuncional a nivel estratégico para la industria retail. Para un horizonte de planificación semanal, el problema consiste en diseñar un plan de capacitación idóneo para una fuerza laboral conocida y que inicialmente está capacitada para trabajar en un solo departamento (es decir, personal especialista), a través de estructuras *k-chaining* donde los empleados polifuncionales puedan ser entrenados en dos o más departamentos y donde cada empleado debe trabajar un número determinado de horas semanales según lo especificado en su contrato. La solución a este modelo debe proporcionar una

solución eficiente al problema de asignación que nos indicará cuantas horas semanales debe trabajar cada empleado en los departamentos donde recibió capacitación. La solución del problema decidirá cuántos empleados deben ser especialistas y cuántos polifuncionales, cuántas habilidades adicionales debe adquirir cada empleado polifuncional, y bajo qué niveles de incertidumbre de la demanda es más beneficioso una política 2-chaining o k-chaining con k≥2.

Nuestra formulación considera los siguientes supuestos: (1) La demanda semanal por departamento tiene una distribución de probabilidad conocida y se asume correlación cero entre las demandas por departamento. (2) La demanda del personal para cada departamento puede ser parcialmente satisfecha. Esto implica que el costo de subdotación de personal se incluye en la función de costo total. (3) se incorpora también los costos de sobredotación de personal y capacitación en la función de costo total. (4) Se supone que los costos de subdotación, sobredotación y capacitación son los mismos para todos los departamentos. (5) No hay ausentismo de personal. (6) Todos los empleados tienen el mismo contrato y, por lo tanto, trabajan la misma cantidad de horas semanales. (7) El problema determinístico de asignación de personal es totalmente equilibrado, es decir, que las horas disponibles para la asignación en cualquier departamento son iguales al valor en horas de la demanda media de ese departamento. (8) Inicialmente todos los empleados son especialistas (9) Los empleados polifuncionales pueden trabajar en dos o más departamentos. (10) Los empleados son homogéneos, lo que significa que la productividad individual de cada uno es la misma.

4 Metodología

4.1 Modelo de optimización determinista usando enfoque *k-chaining* con k≥2

En esta subsección presentamos el MPLEM para resolver el problema de asignación de personal con encadenamiento como se describió anteriormente. A continuación, se presenta la notación matemática del problema.

Conjuntos

I Empleados de la tienda, indexado por i

L Departamentos de la tienda, indexado por l

S Escenarios de demanda, indexado por s

I_l Empleados bajo contrato en el departamento l, indexado por i, $\forall l \in L$

Parámetros

$r_l(s)$ Demanda aleatoria semanal en horas para el departamento l y escenario s, $\forall l \in L, s \in S$

$\overline{r_l}$ Valor medio de la demanda de horas semanales en el departamento l, $\forall l \in L$

c Costo de capacitación de un empleado para trabajar en cualquier departamento

u Costo de escasez de personal por hora en cualquier departamento

b Costo de excedente de personal por hora en cualquier departamento

h Número de horas semanales que el empleado debe trabajar según contrato laboral

m_i Departamento para el cual el empleado *i* fue inicialmente capacitado, $\forall i \in I$

Variables

x_{il} Igual a 1 si el empleado *i* es capacitado para trabajar en el departamento *l*, 0 de lo contrario, $\forall i \in I, l \in L$

v_i Número de habilidades adicionales del empleado *i*, $\forall i \in I$

ω_{il} Horas semanales de trabajo asignadas al empleado *i* en el departamento *l*, $\forall i \in I, l \in L$

κ_l Escasez de personal en horas semanales en el departamento *l*, $\forall l \in L$

δ_l Excedente de personal en horas semanales en el departamento *l*, $\forall l \in L$

El MPLEM determinista se puede formular de la siguiente manera:

$$Min \quad \underbrace{\sum_{i \in I} \sum_{l \in L: l \neq m_i} c x_{il}}_{(a)} + \underbrace{\sum_{l \in L} u \kappa_l}_{(b)} + \underbrace{\sum_{l \in L} b \delta_l}_{(c)} \tag{1}$$

s.a.

$$\sum_{i \in I} \omega_{il} + k_l - \delta_l = \overline{r_l} \qquad \forall l \in L \tag{2}$$

$$\sum_{l \in L} \omega_{il} = h \qquad \forall i \in I \tag{3}$$

$$\omega_{il} \leq h x_{il} \qquad \forall i \in I, l \in L \tag{4}$$

$$x_{il} = 1 \qquad \forall i \in I, l \in L : l = m_i \tag{5}$$

$$v_i = \sum_{i \in L: l \neq m_i} x_{il} \qquad \forall i \in I \tag{6}$$

$$\sum_{i \in I_l} v_i = \sum_{i \in \{I - I_l\}} x_{il} \qquad \forall l \in L \tag{7}$$

$$x_{il} \in \{0,1\} \qquad \forall i \in I, l \in L \tag{8}$$

$$v_i \geq 0 \qquad \forall i \in I \tag{9}$$

$$\omega_{il} \geq 0 \qquad \forall i \in I, l \in L \tag{10}$$

$$\kappa_l, \delta_l \geq 0 \qquad \forall l \in L \tag{11}$$

La función objetivo (1) minimiza los siguientes costos semanales: (a) capacitación de empleados en departamentos adicionales; (b) subdotación; y (c) sobredotación. Las restricciones (2) explican el cumplimiento de la demanda, y nos permiten calcular el nivel de sobre/subdotación de personal asociado con cada departamento. Las restricciones (3) aseguran que los empleados trabajen exactamente la cantidad de horas requeridas por su contrato. Las restricciones (4) imponen que cada empleado pueda ser asignado a trabajar en, y solo en, departamentos para los que han sido capacitados. Las restricciones (5) determinan el departamento para el que se capacitó originalmente a cada empleado. Las restricciones (6) indican, para cada empleado, cuántas habilidades tiene

en total. Las restricciones (7) garantizan para cada departamento *l*, que exista igualdad entre la cantidad de habilidades adicionales de los empleados propios que son entrenados para trabajar en otro departamento de la tienda $\left(\sum_{i\in I_l} v_i\right)$ y la cantidad de empleados pertenecientes a otros departamentos que recíprocamente fueron entrenados para trabajar en el departamento l $\left(\sum_{i\in\{I-I_l\}} x_{il}\right)$; estas restricciones garantizan la formación de cadenas cerradas (CLC y / o CSC). Finalmente, las restricciones (8) - (11) definen el dominio de cada variable.

4.2 Formulación estocástica de dos etapas

Esta subsección presenta una reformulación del modelo determinístico presentado en la Subsección 4.1 a un modelo de programación estocástica a dos etapas (TSSO) considerando demanda estocástica. En esta formulación hay variables de primera y de segunda etapa. Las variables de la primera etapa, x_{il} y v_i están relacionadas con las decisiones sobre capacitar a los empleados en diferentes departamentos. Las variables de la segunda etapa, $\omega_{il}(s), \kappa_l(s),$ y $\delta_l(s),$ son los ajustes operativos que se hacen una vez se observa la demanda incierta en cada departamento. Es decir, una vez conocida las realizaciones de la demanda, pueden producirse sobredotación o subdotación de personal.

A continuación, presentamos la versión TSSO de la formulación (1) - (11), usando el método comúnmente conocido como *Sample Average Approximation* (SAA) [28].

$$Min \quad \underbrace{\sum_{i\in I}\sum_{l\in L:l\neq m_i} cx_{il}}_{primera-etapa} + \underbrace{\frac{1}{|S|}\left[\sum_{s\in S}\sum_{l\in L} u\kappa_l(s) + \sum_{s\in S}\sum_{l\in L} b\delta_l(s)\right]}_{segunda-etapa} \tag{12}$$

s.a.

$$\sum_{i\in I} \omega_{il}(s) + k_l(s) - \delta_l(s) = \overline{r}_l(s) \qquad \forall l \in L, s \in S \tag{13}$$

$$\sum_{l\in L} \omega_{il}(s) = h \qquad \forall i \in I, s \in S \tag{14}$$

$$\omega_{il}(s) \leq h x_{il} \qquad \forall i \in I, l \in L, s \in S \tag{15}$$

$$x_{il} = 1 \qquad \forall i \in I, l \in L : l = m_i \tag{16}$$

$$v_i = \sum_{i\in L:l\neq m_i} x_{il} \qquad \forall i \in I \tag{17}$$

$$\sum_{i\in l_l} v_i = \sum_{i\in\{I-I_l\}} x_{il} \qquad \forall l \in L \tag{18}$$

$$x_{il} \in \{0,1\} \qquad \forall i \in I, l \in L \tag{19}$$

$$v_i \geq 0 \qquad \forall i \in I \tag{20}$$

$$\omega_{il}(s) \geq 0 \qquad \forall i \in I, l \in L, s \in S \tag{21}$$

$$\kappa_l(s), \delta_l(s) \geq 0 \qquad \forall l \in L, s \in S \tag{22}$$

La función objetivo (12) busca minimizar el costo de capacitación semanal (decisiones de la primera etapa) y el costo semanal esperado de sobre/subdotación de personal (decisiones de la segunda etapa). En la versión de TSSO, las decisiones sobre cuáles empleados serán capacitados en dos o más departamentos, están asociadas a la primera etapa del problema estocástico. Estas decisiones afectarán los niveles de sobre/subdotación de personal; los cuales son decisiones asociadas a la segunda etapa del problema. Por lo tanto, el objetivo en el enfoque TSSO es elegir las variables de la primera etapa que minimizan la suma de los costos de la primera etapa y el valor esperado de los costos de la segunda etapa.

Con respecto a las restricciones (2) - (11) presentadas en la formulación determinista, las restricciones (2) - (4) y (10) - (11) se modificaron para incorporar explícitamente la incertidumbre de la demanda. Tenga en cuenta que todas estas restricciones implican solo variables de segunda etapa. Por lo tanto, las restricciones (5) - (9) no recibieron ninguna modificación porque están asociadas con variables de primera etapa. Además, tenga en cuenta que la interpretación de las restricciones (13) - (22) y las restricciones (2) - (11) es la misma.

A diferencia de la formulación (4.1), la formulación (4.2) incorpora explícitamente la incertidumbre en la demanda. Esto permite que las decisiones sobre la polifuncionalidad sean factibles y robustas ante perturbaciones en la demanda pronosticada. Finalmente, esto implica que la formulación determinista (4.1) puede inducir a una inadecuada planificación del personal y a mayores costos laborales.

5 Caso de estudio

5.1 Requerimientos de datos

Esta subsección describe las características y la configuración de los conjuntos y parámetros utilizados en este estudio. La base de datos utilizada contiene datos reales y simulados, que se deriva de una tienda de retail ubicada en Santiago de Chile. A continuación, presentamos una descripción de ambos conjuntos de datos.

Datos reales. El caso de estudio considera una tienda con 6 departamentos y 30 empleados, es decir, $|L| = 6$ y $|I| = 30$. Todos los empleados tienen el mismo contrato, tal que todos los empleados deben trabajar 45 horas por semana, es decir, $h = 45$. Para el departamento 1 (D1), $\overline{r}_1 = 315$ (es decir, 7 empleados) mientras que para los otros 5 departamentos: (D2), $\overline{r}_2 = 225$; (D3), $\overline{r}_3 = 135$; (D4), $\overline{r}_4 = 135$; (D5), $\overline{r}_5 = 180$ y (D6), $\overline{r}_6 = 360$. En cuanto a los parámetros de costo, asumimos un costo mínimo de capacitación por empleado $(c = US\$1 - sem/empleado)$ [29]. Los costos asociados con la sobredotación y subdotación de personal son iguales a $u = US\$60/h$ y $b = US\$15/h$, respectivamente.

Datos simulados. Se consideran dos tipos de datos simulados asociados a la demanda incierta, estos son: (i) datos dentro de la muestra (*in-sample*) y (ii) datos fuera de la muestra (*out-of-sample*). Los datos dentro de la muestra se refieren a los datos iniciales que se utilizarán para encontrar las soluciones a las variables de primera etapa usando

el enfoque TSSO. Mientras que los datos fuera de la muestra se refieren a los datos que se reservarán para comparar el rendimiento de las soluciones generadas por el enfoque de optimización TSSO y los enfoques miopes: Polifuncionalidad Cero (PC) y Polifuncionalidad Total (PT). El enfoque miope PC representa un experimento donde todos los empleados se mantienen como especialistas y, por lo tanto, no hay empleados polifuncionales. El enfoque miope PT representa un experimento donde todos los empleados serán polifuncionales y pueden trabajar en cualquier departamento de la tienda.

En ambos tipos de datos simulados, y con el objetivo de evaluar cómo funcionan las estructuras de polifuncionalidad con el enfoque *k-chaining* con $k \geq 2$ y diferentes niveles de incertidumbre, nosotros consideramos nueve niveles de variabilidad para la demanda en cada departamento de la tienda: $CV = 5, 10, 20, 30, 40, 50, 60, 70, 80\%$.

Para ambos conjuntos de datos, se considera que las realizaciones no negativas de la demanda estocástica para cada departamento de la tienda siguen una distribución normal, y para evitar generar valores de demanda atípicos las funciones de distribución de probabilidad se truncan en los percentiles 5 y 95 (es decir, representamos el 90% de la distribución de datos). Para los parámetros aleatorios de las horas semanales de demanda $r_i(s)$, utilizamos una simulación de Monte Carlo para generar aleatoriamente $|S| = 1000$ y $|S| = 10000$ escenarios para los datos dentro y fuera de la muestra respectivamente.

6 Resultados y discusión

6.1 Análisis dentro de la muestra

Los resultados y las discusiones de este análisis se dividen en las siguientes dos subsecciones: Tiempos computacionales y tamaño de los modelos, y ¿Cuánta polifuncionalidad se debe agregar?

Tiempos computacionales y tamaño de los modelos. El modelo TSSO (12) – (22) se escribió en AMPL y el problema se resolvió utilizando el software comercial CPLEX que se ejecuta a través de NEOS server durante 8 h (restrictivo). Para cada CV, el enfoque TSSO se ejecutó considerando 1000 realizaciones de la demanda en cada uno de los 6 departamentos de la tienda.

La Tabla 2, para cada CV, informa los tiempos computacionales obtenidos por el enfoque TSSO (en horas) y el modelo determinista (DT) (en segundos). A su vez, la tabla muestra el tamaño de los modelos. En general, los tiempos de solución del enfoque TSSO son mucho más altos como resultado de la diferencia en el tamaño de los modelos. Cabe aclarar que debido a que las decisiones abordadas en este estudio son a nivel estratégico con un horizonte de planificación semanal los tiempos que arroja el modelo TSSO se consideran razonables. Adicionalmente, considerando todos los CV, nosotros reportamos que los gaps de optimalidad con el enfoque TSSO fueron menores al 0,05%.

Tabla 2. Tiempos computacionales y tamaño de los modelos

	Tiempo en CPU								Tiempo promedio	Restricciones	Variables binarias	Variables continuas
	5%	10%	20%	30%	50%	60%	70%	80%				
TSSO	1,18	8	8	8	6,3	8	8	8	6,935	216066	150	192060
DT	1,48								1,48	282	150	252

¿Cuánta polifuncionalidad se debe agregar? El objetivo en esta subsección es responder a la siguiente pregunta táctica: ¿Cuántos empleados deben ser polifuncionales y en cuántos departamentos adicionales? Dado este propósito, determinamos el número óptimo de empleados polifuncionales requeridos para cada departamento y nivel de variabilidad en la demanda (CV). En la Figura 3 se muestra (en colores) el número óptimo de empleados polifuncionales por departamento y CV, y se incluyen las siguientes cuatro métricas. Primera, el porcentaje de empleados polifuncionales en relación con el número total de empleados, %EP. Segunda, el porcentaje de empleados polifuncionales entrenados en un departamento adicional y, por lo cual, capacitados en un total de dos departamentos, %EP(2). Tercera, el porcentaje de empleados polifuncionales entrenados en dos departamentos adicionales y, por lo cual, capacitados en un total de tres departamentos, %EP(3). Cuarta, el porcentaje de polifuncionalidad total (%PT), que se refiere al número de habilidades adicionales capacitadas, en relación con el número máximo teórico factible.

		Demanda media						%EP	%EP(2)	%EP(3)	%PT
		315	225	135	135	180	360				
	5	1	1	1	1	1	1	20	20	0	4
	10	2	1	1	1	1	2	27	27	0	5
	20	3	2	1	1	2	3	40	40	0	8
	30	4	3	2	2	2	5	60	60	0	12
%CV	40	5	4	2	2	3	6	73	73	0	15
	50	6	4	3	3	4	7	90	90	0	18
	60	7	5	3	3	4	8	100	90	10	22
	70	7	5	3	3	4	8	100	70	30	26

		D1	D2	D3	D4	D5	D6				
		Departamento									

Figura 3. Métricas de polifuncionales asociadas a cada nivel de variabilidad en la demanda.

La figura muestra como la cantidad de empleados polifuncionales de la tienda aumenta a medida que aumenta el valor de la demanda media de un departamento y el nivel de variabilidad (CV). También se observa que cuando la variabilidad es la más baja (CV=5%), solo se requiere un empleado polifuncional por departamento a pesar del supuesto de costo mínimo de capacitación. Este resultado puede interpretarse como la inversión mínima necesaria en polifuncionalidad (es decir, EP = 20% y PT = 4%). A su vez, cuando la variabilidad de la demanda es la más alta (CV=80%), el número óptimo de empleados polifuncionales por departamento es igual a su personal total. De hecho, para CVs iguales o mayores al 60% se requiere que el 100% de los empleados sean polifuncionales.

Por otro lado, se puede notar que para un CV del 5% al 50% el total de empleados polifuncionales está capacitado en un total de dos departamentos (es decir, un departamento adicional). Esto indica que para estos escenarios de variabilidad en la demanda una política *2-chainning* entrega el máximo beneficio. Sin embargo, para altos niveles de variabilidad en la demanda, CV= 60,70 y 80%, se requieren empleados polifuncionales capacitados en uno o hasta en dos departamentos adicionales. Por lo tanto, para ningún CV se requieren empleados polifuncionales entrenados en tres o más departamentos adicionales (es decir, 4 o más departamentos en total). Esto indica que valores de k=2 y k=3 en las políticas *k-chaining* ofrecen los resultados más costo-efectivos.

Adicionalmente, para cada CV, la Figura 4 presenta de forma detallada la cantidad de empleados polifuncionales en la tienda que están entrenados en un total de dos departamentos o tres departamentos.

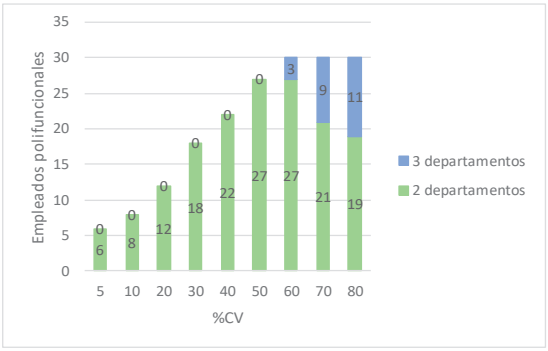

Figura 4. Número de empleados polifuncionales en dos o tres departamentos para cada CV.

6.2 Análisis fuera de la muestra

El objetivo en esta subsección es hacer comparaciones justas entre las soluciones del enfoque TSSO y los enfoques miopes PT y PC. La Tabla 3 presenta para cada combinación, de enfoque y CV, los valores de las métricas asociadas a los análisis dentro y fuera de la muestra. Las columnas 2,3,4 y 5 muestran los requerimientos de polifuncionalidad entregados en el análisis dentro de la muestra (es decir, %EP, %EP(2), %EP(3) %PT) y reportados en la Figura 3. Las columnas 6 y 7 están asociados al análisis fuera de la muestra, los cuales se basan en los 10000 escenarios de demanda generados a través de la simulación Monte Carlo. La columna 6 muestra el porcentaje de ahorro en el costo semanal promedio de sobre/subdotación de personal ($\%\overline{SSA}$) que se obtiene para cada enfoque. La columna 7 reporta el costo total semanal promedio incurrido $(\overline{\varphi})$ en cada enfoque.

Note que, la métrica $\%\overline{SSA}$ permite evaluar la fiabilidad y robustez de las soluciones entregadas por cada enfoque. Por un lado, el enfoque miope PT siempre exhibirá la mayor fiabilidad y robustez posible, es decir, logra la máxima reducción posible en el costo semanal de sobre/subdotación de personal ($\%\overline{SSA} = 100$). Sin embargo, es el enfoque más conservador, pues exige la inversión máxima en polifuncionalidad (%EP =%PT = 100%). Por el contrario, el enfoque miope PC siempre reporta el costo total

promedio más alto, debido a que no proporciona ningún nivel de protección ante la variabilidad de la demanda (es decir, %ME =%TM = $\%\overline{SSA}$ = 0%.). Respecto al enfoque TSSO, al igual que el enfoque PT, este también logra el máximo ahorro en el costo semanal de sobre/subdotación de personal ($\%\overline{SSA}$ = 100) para cada CV, pero con una inversión mucho menor en polifuncionalidad. Por lo tanto, el enfoque TSSO siendo menos conservador que el enfoque PT, logra para cada CV el costo total promedio más bajo. Este resultado es muy interesante, pues mediante el enfoque TSSO con *k-chaining*, se cosecha el 100% de los beneficios potenciales alcanzables, pero con una inversión mucho menor, lo cual lo hace rentable y atractivo para los tomadores de decisión.

Tabla 3. Métricas de desempeño para cada enfoque y CV

Enfoque	Métricas						Enfoque	Métricas					
	dentro de la muestra				fuera de la muestra			dentro de la muestra				fuera de la muestra	
	%EP	%EP(2)	%EP(3)	%PT	$\%\overline{SSA}$	$\bar{\varphi}$ (US$)		%EP	%EP(2)	%EP(3)	%PT	$\%\overline{SSA}$	$\bar{\varphi}$ (US$)
	CV=5%							CV=10%					
TSSO	20	20	0	4	100	709	TSSO	27	27	0	5	100	1426

7 Conclusiones y futura investigación

Este estudio presenta una nueva versión del problema semanal de asignación de personal polifuncional con encadenamiento y demanda incierta. Nuestros resultados brindan una base para construir políticas de polifuncionalidad que respondan a dos preguntas fundamentales: cuánta y cómo agregarla. Respecto a la primera pregunta, los resultados mostraron que incluso cuando el costo de capacitación es mínimo no se necesita la polifuncionalidad total para asegurar los máximos beneficios de la polifuncionalidad. Además, que el número de empleados polifuncionales requeridos aumenta a medida que la demanda media de un departamento y el coeficiente de variación de la demanda son mayores. Para la segunda pregunta, los resultados mostraron que la mejor forma de agregar polifuncionalidad es generar estructuras de personal que combinen personal especializado y personal polifuncional.

Por otro lado, los resultados nos ayudan a concluir que el enfoque TSSO exhibe excelentes rendimientos al lograr el 100% de los beneficios potenciales de la polifuncionalidad total, pero con una inversión menor. También los resultados demuestran que, para escenarios de variabilidad de la demanda menores o iguales al 50%, una política *2-chainning* reporta los máximos beneficios posibles. Pero con niveles de variabilidad mayores al 50% se requiere de mayores niveles de polifuncionalidad, por lo cual en estos escenarios es más beneficioso el uso de políticas *k-chainning* con $k \geq 2$. Sin embargo, en nuestro caso de estudio, se encontró que no se necesitan empleados polifuncionales que estén capacitados en más de tres departamentos para conseguir los beneficios máximos.

En cuanto a la investigación futura, los nuevos estudios pueden relajar algunos de nuestros supuestos. Por lo tanto, la metodología podría modificarse para: (1) Evaluar una política de flexibilidad que considere simultáneamente decisiones de polifuncionalidad y contratación de personal. (2) Considerar que los empleados son heterogéneos, es decir, que la productividad individual de cada uno pueda variar dependiendo de la cantidad de departamentos en los cuales se encuentre capacitado. (3) Permitir que los costos de sobredotación, subdotación y capacitación varíen de un departamento a otro.

Resumo. A incerteza está presente na maioria dos processos produtivos. Estimar a demanda, gerenciar os recursos e preparar-se para enfrentar os riscos inerentes às oscilações de mercado é fundamental para a permanência da empresa no cenário competitivo atual. Nos últimos anos, a comunidade científica tem demonstrado interesse nos aspectos relacionados à previsão do comportamento de parâmetros estocásticos em sistemas de otimização. Desta forma, a fim de perceber a importância que pesquisadores e periódicos dão ao assunto e quais as áreas de maior aplicação, escolheu-se, como método de pesquisa, a Revisão Sistemática de Literatura. A partir disso, como objetivo geral da pesquisa, buscou-se compreender como a Simulação de Monte Carlo (SMC), incorporada à Programação Linear (PL), pode contribuir na percepção e incorporação da variabilidade nos processos de produção. Foram identificados 113 artigos, publicados entre 2015 e 2019, os quais foram analisados a fim de estimar em que problemas essas ferramentas são mais utilizadas. Também foi identificado como se dá a compreensão dos fenômenos produzidos pela aleatoriedade e que ferramentas podem ser incorporadas ao processo de otimização visando uma compreensão mais abrangente. Por fim, a análise dos artigos selecionados revelou que as áreas que mais utilizam a SMC incorporada à PL estão relacionadas às pesquisas em energia renovável e sustentabilidade.

Palavras-chave: Incerteza· Simulação de Monte Carlo· Programação Linear· Revisão de Literatura.

1 Introdução

A reconfiguração do mercado econômico, estimulada pela globalização, determina que as instituições adaptem suas estratégias de gestão a fim de que possam manter a competitividade. A adoção de novas tecnologias nos processos produtivos e a modernização das ferramentas de gestão podem ser a base para a consolidação das empresas nos panoramas nacional e internacional [1–5].

Na teoria econômica a instituição é considerada uma unidade produtiva que atua na transformação de insumos em bens e serviços. A necessidade da atualização e

otimização de procedimentos objetiva a manutenção financeira e a provisão de lucros, consecutivamente há o crescimento da empresa no mercado [6].

Contudo, as incertezas de demanda futura, de preços de mercado, de recursos disponíveis e a necessidade de redução dos custos operacionais motiva as instituições quanto à busca do equilíbrio econômico-financeiro [7–10]. A atenção dos pesquisadores e especialistas está voltada à incorporação de novos modelos de produção a fim de otimizar processos, minimizando perdas e maximizando lucros [4, 11, 12].

Entretanto, a sensibilização por melhorias não está restrita à eficiência econômica. Ela também abrange os aspectos ambientais e sociais. Prever o comportamento incerto dos recursos naturais, a emissão de poluentes e as questões relacionadas à saúde e ao bem-estar passaram a integrar às responsabilidades dos gestores no momento da tomada de decisão [13–16].

Corroborando com o exposto, no campo da engenharia a empresa é uma unidade técnica que executa processos de transformação. Embora seja caracterizada quantitativamente como um conjunto de parâmetros e coeficientes, a instituição permeia as relações entre o material, o humano e o energético, sendo um dependente do outro [6].

Nesta perspectiva, a Pesquisa Operacional (PO) pode ser utilizada como apoio nos processos decisórios. Por meio de modelos matemáticos é possível simular e avaliar problemas reais de forma criteriosa, considerando os principais parâmetros e suas influências nos sistemas, sejam eles simples ou robustos. As técnicas de otimização auxiliam o tomador de decisão no controle das variáveis do projeto e na administração dos recursos disponíveis [5, 17–19].

Diante do exposto, o objetivo desta pesquisa é explorar o uso da Simulação de Monte Carlo (SMC) como ferramenta de avaliação da incerteza e variabilidade em problemas de Programação Linear (PL). Por meio de revisão sistemática de literatura, pretende-se verificar quais são as situações em que essa ferramenta está sendo empregada, além de apurar seus benefícios e limitações.

Este artigo está estruturado em cinco seções. Na segunda seção, será realizada a contextualização teórica acerca do tema. Na sequência, a terceira seção apresentará a estratégia de busca e de seleção dos artigos para compor o banco de dados. A quarta seção constituirá na análise e apresentação das pesquisas que utilizaram SMC para avaliar a aleatoriedade em suas situações-problema. Serão discutidos os resultados decorrentes das observações na quinta seção para que na sexta, e última seção, possam ser apresentadas as considerações finais e perspectivas sobre pesquisas futuras.

2 Referencial Teórico

2.1 Pesquisa Operacional

A PO surgiu durante a Segunda Guerra Mundial, a partir da necessidade de encontrar solução para problemas militares de ordem logística, estratégica e tática. À época, cientistas foram convocados para estudar situações relacionadas à otimização dos escassos recursos disponíveis [17, 18, 20, 21].

Em 1947, George Bernard Dantzig e sua equipe formularam e resolveram um Problema de PL para a Força Aérea Militar norte americana. Os estudos realizados pela

equipe de Dantzig embasaram-se nas pesquisas do matemático russo Kantorovich e proporcionaram o desenvolvimento do Algoritmo Simplex, de considerável relevância nos problemas de otimização atuais [5, 18, 22].

Os métodos e as ferramentas da PO tratam tanto os modelos determinísticos quanto os estocásticos. Os primeiros possuem parâmetros constantes e conhecidos e são resolvidos por meio de sistema de equações; e os modelos estocásticos, que retratam a maioria dos problemas reais de PO, apresentam a incerteza agregada a um ou mais parâmetros. Neste último caso, são encontradas mais do que uma solução, sem a obrigatoriedade de definir a ótima [17, 20, 23].

Além da escolha da ferramenta ideal, que é balizada pela complexidade de cada problema, os especialistas podem executar os modelos com o auxílio de pacotes de otimização e/ou softwares auxiliares. Para a resolução de Problemas Lineares, Não Lineares ou variações, os pacotes de otimização mais conhecidos são: CPLEX®, LINDO®, LINGO®, OSL®, XPRESS®. Já os softwares utilizados são: GAMS®, @Risk®, AMPL®, RStudio® entre outros [18].

2.2 Programação Linear

A PL é um dos métodos da PO mais utilizados na otimização de problemas e tem por objetivo dar suporte à tomada de decisão seja ela estratégica, tática ou operacional. O modelo é expresso por uma função linear: a função objetivo, de forma que a cada função objetivo sejam atribuídas condições operacionais, também chamadas de restrições [17, 20, 21, 23].

O modelo geral de PL [17, 18], utilizado para otimizar a função objetivo, pode ser representado como segue :

Otimizar:

$$Z = \sum_{j=1}^{n} c_j x_j \qquad (1)$$

sujeito a:

$$\sum_{j=1}^{n} a_{ij} x_j \geq b_i \qquad i = 1, 2, \dots, p \qquad (2)$$

$$\sum_{j=1}^{n} a_{ij} x_j = b_i \qquad i = p+1, p+2, \dots, m \qquad (3)$$

$$x_j \geq 0, \; j = 1,2, \dots, n \qquad (4)$$

$$x_j \in \Re, \; j = q+1, q+2, \dots, q+n \qquad (5)$$

sendo:

A = $\{a_{ij}\}$ é a matriz de restrições e a_j equivale à j-ésima coluna de A;

x = (x_j) e c = (c_j), ambos com j ∈ N são vetores coluna e linha de n componentes, respectivamente;

d = (d_i) com i ∈ M é vetor coluna de m componentes;

M = {1, 2, ..., m} é o conjunto dos índices das restrições do problema e;

N = {1, 2, ..., n} o conjunto dos índices das variáveis.

Após a construção do modelo matemático, o qual representa o problema de PL, é possível determinar a solução ótima. Para isso, podem ser utilizados diversos algoritmos, o mais antigo e ainda mais usual é o Algoritmo Simplex. Vários são os setores que aplicam a PL para a otimização de problemas, entre eles estão o rodoviário, naval, industrial, saúde, comércio, energia, entre outros [18, 24–27].

A PL pode ser utilizada tanto para modelos determinísticos quanto estocásticos.

Embora os modelos determinísticos sejam mais fáceis de tratar em virtude da precisão de seus parâmetros, nem sempre refletem a realidade. Em decorrência disso, prevendo a variabilidade dos parâmetros no decorrer de um processo, considera-se mais efetiva a utilização dos modelos estocásticos [13, 16, 28–30].

Nesse sentido, quando há a variabilidade dos parâmetros de um sistema, é necessário que seja adotada alguma ferramenta de simulação ou previsão da aleatoriedade. A SMC pode ser efetiva para a composição do modelo e a previsão dos riscos e incertezas [31–33].

2.3 Simulação De Monte Carlo (SMC)

A SMC é uma ferramenta confiável para estimativa de incertezas. É frequentemente utilizada na física, matemática e engenharia, especificamente na análise de probabilidade e estatística em virtude da alta precisão e simplicidade na representação da aleatoriedade [7, 33, 34].

Os algoritmos fundamentados na SMC são exibidos como valores intervalares, usualmente apresentados como funções de distribuição de probabilidades (FDPs). A representação aleatória pode ser obtida por meio de tabelas ou softwares específicos e o processo ocorre a partir de iterações que resultam em um conjunto de distribuição de resultados [32, 35–37].

Para tratar as incertezas identificadas nos problemas que surgem tanto dentro da indústria quanto no mercado de serviços, podem ser utilizadas inúmeras abordagens. Contudo, a SMC aliada aos algoritmos da PL estão entre as mais usuais quando é necessário realizar uma avaliação criteriosa de procedimentos operacionais mais complexos [28, 38, 39].

Esta técnica permite a análise do comportamento estocástico das variáveis de input e a compreensão das variáveis de output. Cada vez mais utilizada em virtude do aprimoramento computacional, a SMC assegura que as incertezas e os riscos estarão incorporados na análise de todos os cenários possíveis e na tomada de decisão [5, 40, 41].

3 Materiais e Métodos

Caracterizada como teórico-conceitual [42], esta pesquisa objetiva a busca e seleção de artigos publicados entre 2015 e julho 2019 para a coleta de dados sobre a aplicabilidade da SMC em problemas de PL (PPL). Por meio desta pesquisa bibliográfica [43], pretende-se verificar o que já foi produzido pela comunidade científica sobre a temática, apontar lacunas e delinear pesquisas futuras.

Esta pesquisa pode ser considerada exploratória e descritiva, pois por meio da seleção de artigos em bases de dados, previamente selecionadas, pretende-se a construção do conhecimento e a posterior apresentação do portifólio encontrado. Quanto à abordagem, este trabalho pode ser enquadrado como quali-quantitativo devido aos processos de seleção, análise e quantificação das produções científicas [44].

Como protocolo de pesquisa foi utilizado o Método *Preferred Reporting Items for Systematic review and Meta-Analysis Protocols* (PRISMA-P), na tradução literal Principais Itens para Relatar Revisões sistemáticas e Meta-análises. Esta metodologia

consiste em 17 passos destinados a facilitar a organização e elaboração da Revisão Sistemática de Literatura (RSL) e se caracteriza por ser um método íntegro e transparente, que exige justificativa, hipótese e etapas bem definidas [45].

O processo de revisão teve início com a delimitação do problema de pesquisa qual seja, buscar a aplicabilidade da SMC em PPLs. A partir disso, utilizando as palavras-chave "Monte Carlo" e "Linear Programming", procedeu-se a busca por artigos publicados em periódicos de língua inglesa, nas bases *Thomson Reuters Web-of-Science (WoS)*, *Scopus*, *ScienceDirect*, *Emerald Insight* e *SciELO*, por meio do Portal de Periódicos da Capes.

Após o retorno das bases citadas, foram adotadas as seguintes etapas para a elegibilidade dos artigos: (i) excluir os trabalhos duplicados; (ii) excluir os textos que não se caracterizavam como artigos; (iii) excluir artigos que não contemplavam o tema proposto, a partir da leitura do título e do resumo; e (iv) após procedida a leitura completa, houve a exclusão dos artigos não compatíveis com o objetivo desta revisão.

Visando proporcionar uma compreensão mais abrangente do tema e observar as lacunas existentes na literatura, buscou-se extrair dos artigos inclusos no banco de dados, os seguintes elementos: título, ano de publicação, autor(es), periódico, países de origem da publicação, número de citações, objetivo, área em que o tema pertence, ferramentas utilizadas, contribuições, limitações da pesquisa e indicação de trabalhos futuros.

Por fim, o objeto deste estudo consiste na análise, compreensão e apresentação da produção científica selecionada, no apontamento da relevância do conhecimento gerado, na descrição de possíveis dificuldades e resultados e na indicação de tendências de pesquisa neste campo de estudo.

4 Resultados

A partir da busca nas bases selecionadas, foram encontradas 2.592 publicações com as palavras-chave "Monte Carlo" e "Linear Programming". Destas, 123 (4,7%) provinham da base *Thomson Reuters Web-of-Science (WoS)*, 182 (7%) da base *Scopus*, 2.210 (85,3%) da base *ScienceDirect*, 77 (3%) da base *Emerald Insight* e nenhuma publicação foi encontrada na base *SciELO* para o período de 2015 a julho de 2019.

As produções encontradas foram organizadas no software Mendeley®. Esse aplicativo computacional possui ferramentas úteis para o gerenciamento de referências bibliográficas, tais como categorização por pastas, exclusão de arquivos duplicados e suporte à construção de referências na redação de textos.

Nas primeira e segunda etapas foram excluídos, respectivamente, 81 textos duplicados e 463 trabalhos que não se encaixavam na classificação de artigos publicados em periódicos. Desta forma, 2.038 (78,6%) artigos receberam a atenção quanto à leitura do título e resumo. Foi necessário analisar esses dois elementos conjuntamente em razão de que alguns textos não mencionavam os termos de busca no título, contudo somavam na literatura pretendida nesta revisão.

A partir disso, foram selecionados 194 artigos para a revisão integral do texto, dos quais 113 passaram a compor o banco de dados desta Revisão. As publicações estão distribuídas entre 59 periódicos, sendo que os de maior destaque foram: *European Journal of Operational Research* com 12 artigos, *Energy* com 10, *Applied Energy* com 9 e *Journal of Cleaner Production* com 8 artigos.

Em relação às áreas de concentração dos periódicos, observou-se que 21 (35,6%) destinam-se a publicações referentes à conservação do meio ambiente, eficiência energética e sustentabilidade. Contudo, notou-se que além destes, outros 8 periódicos que tem como alvo publicações diversas, também apresentam artigos contemplando esses assuntos. Desta forma, 64 artigos (56,6%) estão relacionados ao mesmo tema.

Quanto aos anos de publicação dos trabalhos, vale ressaltar que o interesse dos autores quanto ao uso da SMC em PPLs é crescente, conforme ilustra a Figura 1. Isto se deve, também, à modernização dos equipamentos de informática que são ferramentas indispensáveis para a previsão de demandas sobre incerteza quando são necessárias milhares de simulações.

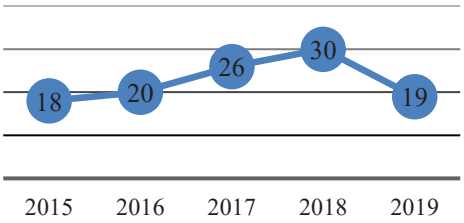

Fig. 1. Distribuição percentual do número de publicações por ano (Fonte: Elaboração própria).

Os 337 autores estão distribuídos entre 37 países, destacando os Estados Unidos com 54 autores, a China com 48 e o Irã com 30 autores. Os países de mais destaque estão relacionados na Figura 2.

Foi identificada a distribuição por continente dos autores para mensurar a intensidade de interesse pelo tema nas diferentes partes do mundo. Desta forma, pode-se observar que a Europa e a Ásia são as regiões em que se concentram a maior parte das publicações com 36% e 35%, respectivamente. Na sequência, o Continente Americano traz 25% das publicações e por fim, a Oceania e a África contribuem com 2% dos artigos cada uma.

Os principais autores têm origem no continente asiático, como percebe-se na Tabela 1. Os três primeiros autores pertencem a um grupo de pesquisa da China e os últimos dois autores são de um grupo de pesquisa das Filipinas. Ambos os grupos se dedicam ao planejamento de sistemas de energia e de abastecimento de água sob incerteza, ao estudo de redes de gerenciamento de carbono, visando a redução da emissão de CO_2 e à implementação de sistemas híbridos de energia.

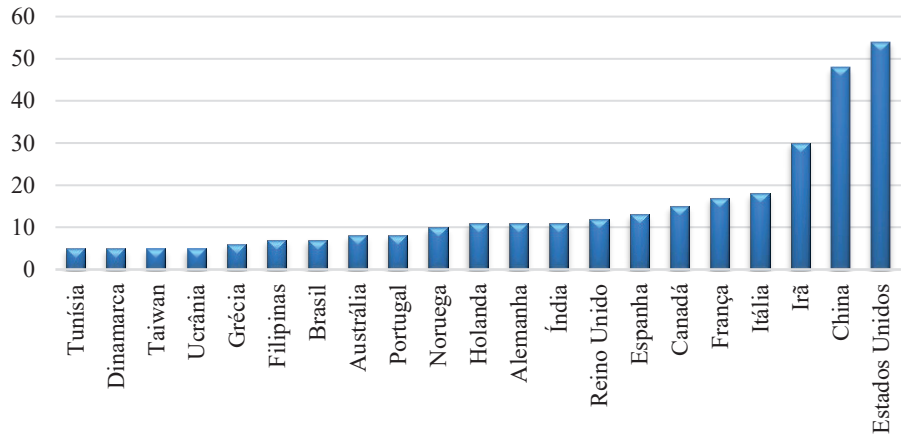

Fig. 2. Distribuição percentual do número de autores por país (Fonte: Elaboração própria)

Autor	Quantidade de artigos	País
Y. P. Li	6	China
L. Yu	5	China
G.H. Huang	5	China
Kathleen B. Aviso	5	Filipinas
Raymond R. Tan	5	Filipinas

5 Discussão

O tratamento da aleatoriedade de parâmetros em problemas de otimização tem sido foco dos pesquisadores de programação matemática nos últimos cinco anos. Ademais, aliada a esta temática surgiu o termo "otimização robusta", o qual se refere a um conjunto de ferramentas com capacidade suficiente de prover resultados em modelos com algum tipo de incerteza [39, 46, 47].

A SMC é amplamente utilizada para avaliar o comportamento incerto de variáveis sobre um determinado problema. Este método contempla sorteios de algarismos pertencentes a determinada distribuição de probabilidades, com base no comportamento prévio das variáveis em certo período [8, 48–50]. Desta forma, organizam-se os diversos cenários que serão analisados a fim de avaliar a sensibilidade do sistema em virtude da aleatoriedade presente nas variáveis [51].

Quase que a totalidade dos problemas identificados nesta revisão utilizou a SMC conjunta à Programação Linear Inteira (PLI) ou Programação Linear Inteira Mista (PLIM) devido à complexidade de seus problemas. O que as diferencia é a caracterização das variáveis e a robustez do

problema. Na PL as variáveis são contínuas, na PLI as variáveis são discretas e a PLIM contempla tanto variáveis discretas quanto contínuas [18].

Marques et *al.* [30] utilizou a SMC integrada à PLIM com o objetivo de integrar decisões estratégicas para o lançamento de produtos farmacêuticos. A técnica se mostrou eficaz tanto na captura dos efeitos da incerteza no sistema quanto no embasamento de decisões acerca da produção, transporte e lançamento dos produtos. Foi possível quantificar os riscos e os ganhos inerentes ao projeto, favorecendo a tomada de decisão.

Wang e Yujie [52] utilizaram a SMC para simular a localização individual de trabalhadores residentes em Baton Rouge - Louisiana e seus empregos. O objetivo foi quantificar o excesso de deslocamento a fim de otimizar o tempo dos funcionários. A metodologia proposta se mostrou favorável ao objetivo do estudo, contudo se fosse aplicada a uma cidade maior, a pesquisa enfrentaria limitações computacionais devido ao tamanho da amostra e o tempo necessário para as simulações. Neste caso, seria necessário agregar mais ferramentas para a resolução.

Com base na análise do comportamento de todos os parâmetros do sistema, fundamental no estudo de problemas de programação, é possível prever quais são as ações necessárias e possíveis para suprir determinada demanda. Exemplificando, Dai e Zheng [53] utilizaram o algoritmo genético híbrido embutido na SMC, a programação *fuzzy* e a programação com restrições de probabilidade para gerenciar uma cadeia fechada de suprimentos (*Closed-loop Supply Chain*).

Não obstante às necessidades de otimizar os recursos visando aumentar os lucros, a empresa que pretende permanecer no cenário econômico atual precisa operar de forma sustentável, socialmente e ambientalmente responsável. Neste ínterim, as preocupações com emissão de poluentes, captação de recursos naturais e descarte de possíveis dejetos de produção estão inseridas no contexto da organização [16, 54–57].

Neste sentido, Jareonkitpoolpol et *al.* [58] propôs o uso de PL, programação com restrição de chance (PRC) e SMC como ferramentas para determinar a fórmula ideal de um fertilizante orgânico-químico. O objetivo do estudo foi produzir um produto que proporcionasse a redução de resíduos químicos no solo e minimizasse o custo final atendendo aos padrões de qualidade, além de reduzir o volume de importações de substâncias químicas.

Khalilzadeh e Derikvand [1] apresentaram um modelo de seleção de fornecedores para uma cadeia de suprimentos considerando o custo total das peças, a qualidade dos itens fornecidos e o nível de emissão de gases de efeito estufa do fornecedor. Neste problema a incerteza é abordada pela programação estocástica e o modelo de múltiplos objetivos é resolvido com base na PL.

Utilizando a PL e a SMC, Tallentire et *al.* [59] propõe a redução nos impactos ambientais decorrentes da produção e consumo de alimentos que abastecem a cadeia produtiva de frangos de corte. O objetivo da pesquisa foi desenvolver uma ferramenta para a formulação de dietas para os animais, projetada para atingir e reduzir categorias de impacto ambiental específicas em duas regiões contrastantes, o Reino Unido e os EUA.

Diante disso, as relações que uma empresa precisa estabelecer com seus fornecedores e clientes, sobre as responsabilidades ambiental e social, não podem ficar restritas aos seus colaboradores e às suas operações. É exigido que os gestores reflitam sobre ações de médio e longo prazo que promovam o fortalecimento da empresa no panorama da sustentabilidade e adotem estratégias para a valorização não somente do lucro, mas também das pessoas e do planeta, conforme prevê a abordagem *triple-botton-line* [13].

No campo da geração de energia, as preocupações não se registram apenas quanto a satisfação da demanda pelo menor custo, mas também na diminuição do impacto ambiental do processo de

geração. Desta forma, Ioannou et *al.* [50] construiu um método de otimização estocástica em vários estágios para determinar o mix ótimo de geração de energia de médio a longo prazo. As incertezas na demanda de energia, nos preços de combustíveis e no custo das tecnologias aplicadas são previstas utilizando a SMC.

Em virtude das alterações naturais provocadas pelo aquecimento global, a atenção de muitos pesquisadores se voltou para o estudo da eficiência no fornecimento de energia limpa, ou seja, com baixa emissão de carbono. Neste sentido, a SMC contribui para a previsão da velocidade dos ventos, da temperatura e demais variáveis que podem influenciar na provisão desta demanda [38, 60–64].

No decorrer desta pesquisa foram quantificadas outras ferramentas que vêm sendo aplicadas na resolução de Problemas de PL, PLI e PLIM a fim de diminuir o tempo computacional, de melhor construir o modelo ou de analisar o sistema com mais precisão. Identificou-se o uso de números *fuzzy* [19, 53, 65, 66], de cadeias de Markov [13, 67], de técnicas de inteligência computacional como algoritmos genéticos [68] e enxame de partículas [69, 70], de metodologias multicritério de apoio à decisão como a Análise Envoltória de Dados (DEA) [71], entre outros.

6 Considerações finais

A partir da reestruturação do comércio e do aumento das relações provocadas pela internacionalização de produtos e serviços, as instituições vêm encontrando novos desafios para manter a competitividade. É crescente a busca pela eficiência na produção, pela adoção de novas tecnologias e pela adequação às exigências do mercado [30, 47, 71, 72]. Além disso, vinculada à questão econômico-financeira está a preocupação com a saúde [24, 56], os recursos naturais [7, 73], a sustentabilidade [59, 74] e a eficiência energética [38, 61, 75].

De forma geral, a SMC é um dos métodos mais simples para prever e tratar as incertezas e associada à PL, contribui para que os recursos possam ser previstos e otimizados. No entanto, os cálculos são mais lentos e exigem maior esforço computacional, uma vez que é necessário contabilizar milhares de observações até chegar ao resultado. Isso corrobora para que sejam indicados métodos híbridos de tratamento da incerteza [8, 15, 49, 71, 76].

Entre os artigos analisados, várias ferramentas foram associadas à SMC na intenção de diminuir o tempo de cálculo como os Métodos Multicritério de Apoio à Decisão [5, 71, 77], os algoritmos genéticos [53], métodos de análise de sensibilidade local e global [51] entre outros.

A partir da escolha de otimização de um recurso específico, sugere-se que seja realizada a comparação de diferentes métodos de tratamento de incertezas, avaliando a precisão e a carga computacional utilizada em cada método.

Abstract. Additive manufacturing (or 3D printing) is considered to be the future of manufacturing. Flexibility, accuracy, rapidness, cost efficiency and lightness are among the advantages those additive manufacturing provides. Astronauts can now produce their own tools and parts in the space with no waiting for another launch. Planning of additive manufacturing machines is a recent hot topic. Efficient use of such resources plays an important role to reduce the costs of additively manufactured parts as well as disseminate this technology making its advantages more apparent. This research addresses the metal additive manufacturing machine scheduling problem with multiple unidentical selective laser melting machines. Machines may have different specifications (dimension, speed, and cost parameters) and parts may have different characteristics (width, length, height, volume, release date and due date). The objective is to obtain a schedule such that total tardiness is minimized and parts are allocated on platforms (or building trays) with no overlap. A genetic algorithm approach is proposed to solve the problem within reasonable times. Results of the computational tests show the promising performance of the proposed method.

Keywords: Metal Additive Manufacturing, 3D Printing, Scheduling, 2D Nesting, Production Planning.

1 Introduction

The manufacturing industry has faced an enormous advancement with the utilization of additive manufacturing (or 3D printing) technologies. *Selective laser melting (SLM)*, *selective laser sintering*, *fused deposition modelling*, *electronic beam melting* and *stereolithography* are some of the most popular ones belonging to this technology. Different from traditional manufacturing techniques which subtract material to produce a final product, 3D printing technologies produce 3D objects through a layer-by-layer production process [1].

Additive manufacturing provides several advantages as opposed to conventional subtractive techniques. Design flexibility, high accuracy, resource efficiency, lightness,

strength and material efficiency are some of those advantages. However, design flexibility is probably the most important one among them. This is because, additive manufacturing allows very complex design structures with the flexibility of layer-by-layer production. With the shift from rapid prototyping to direct digital manufacturing, this feature helps to position additive manufacturing in a higher technology level.

SLM is used to melt and fuse metallic powders together via a high-power density laser. The powder is very fine and deposited on a substrate using a roller with a thickness of usually between 20 μm and 100 μm. The high-power density laser beam melts the 2D cross section of the first layer and so fuses those areas. Afterwards, a new layer of powder is deposited on the substrate and corresponding areas are melted and fused via laser. This layer-by-layer process is repeated until a final product is achieved [2].

The application areas of SLM technique, especially for titanium alloys, are expanding even more recently. SLM has become a widely used additive manufacturing technique to fabricate critical parts (such as turbopumps) used in aerospace. NASA has decided to additively manufacture a rocket engine fuel pump in one piece instead of mounting hundreds of components (including a turbine that spins at over 90,000 rpm) [3]. So that the additively manufactured pump has 45% fewer parts in comparison with traditionally manufactured pumps [1].

The increase in the wide application of AM technologies and demand on 3D printed parts force companies use their resources more efficiently. In this context, considerations for planning and scheduling of additive manufacturing resources are gaining more importance. This research proposes a genetic algorithm (GA) approach to efficiently schedule multiple AM machines for fabricating part orders coming from several customers with the aim of minimizing total tardiness. 2D nesting of parts on the machine platforms (building bed) are also considered as a constraint. Machines are unidentical; their speed, capacity and cost parameters are different. Parts have different dimensions, volume, due dates and release dates. As a unique contribution to literature, this is the first study, which minimizes total tardiness considering 2D nesting of parts, in AM machine scheduling domain.

The remainder of this paper is organized as follows. The following section reviews the literature. Section 3 describes the problem characteristics. Section 4 provides the basic steps of the proposed GA approach. Section 5 reports the results of computational tests and finally Section 6 concludes the paper with future research directions.

2 Literature Review

While the literature on AM and 3D printing is rather extensive, the number of studies on planning and scheduling of AM machines is quite limited. This section reviews the literature on planning and scheduling of AM machines and shows the gap in the literature.

AM machine scheduling problem was introduced by Kucukkoc et al. [4]. They addressed the characteristics of planning production on AM machines and proposed a mathematical formulation to calculate job production times. The model proposed by Kucukkoc et al. [4] aims at increasing the utilization of additive manufacturing

machines considering order delivery times. Another preliminary work on production planning of AM machines belongs to Li et al. [5]. They proposed a mathematical model and two heuristics (i.e. best-fit and adapted best-fit algorithms) to minimize average production cost per volume of material. Following this, the topic attracted many researches. Chergui et al. [6] addressed nesting and scheduling in additive manufacturing. They proposed a mathematical formulation and a heuristic to satisfy demands by customers considering due dates. Kucukkoc et al. [7] proposed a GA approach to minimize maximum lateness in a multiple AM machine environment. Fera et al. [8] developed a modified GA approach for time and cost optimization of single AM machine scheduling problem. Dvorak et al. [9] proposed heuristics for scheduling AM machines considering due dates. Kucukkoc [1] proposed mixed-integer linear programming models to minimize makespan in single, parallel identical and parallel non-identical AM machine scheduling problems. Li et al. [10] introduced the dynamic order acceptance and scheduling problem and proposed a strategy-based metaheuristic decision-making approach. The proposed approach helps companies decide whether to accept an order and when to produce it on which machine.

This survey shows that there is no research in metal additive manufacturing field that minimizes total tardiness while considering 2D nesting constraints. Thus, this paper contributes to literature proposing a GA approach to minimize total tardiness while ensuring 2D nesting feasibility.

3 Problem Definition

As clearly described by Kucukkoc [1], the problem of production planning and scheduling of metal AM machines is NP-Hard to solve. A group of AM machines in different specifications (i.e. width, length, speed, etc.) are available to produce parts received from individual customers. The parts also have different characteristics (i.e. width, length, height, volume, and due date) which need to be taken into account to obtain a feasible and efficient solution. The problem is to group parts into batches (called jobs) and allocate them to machines such that a performance criterion is optimized. The performance criterion aimed in this research is total tardiness minimization.

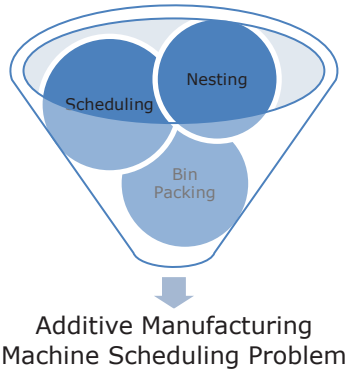

Fig. 1. Three basic components of the AM machine scheduling problem.

Although the problem can be supposed to be a classical bin packing problem, actually it is not. This is a multi-faced problem which involves many different problems inside: *bin packing*, *scheduling* and *nesting* (see Fig. 1). Furthermore, grouping parts and assigning them to machines can be considered a *batch scheduling* problem. However, Kucukkoc [1] shows why this problem cannot be considered as a batch scheduling problem.

Fig. 2 depicts a schematic representation of the addressed problem in an environment with multiple AM machines of SLM type. The two questions which need to be answered are as follows:

- Which parts will be grouped together into which job batch?
- Which job batch will be processed when and on which machine?

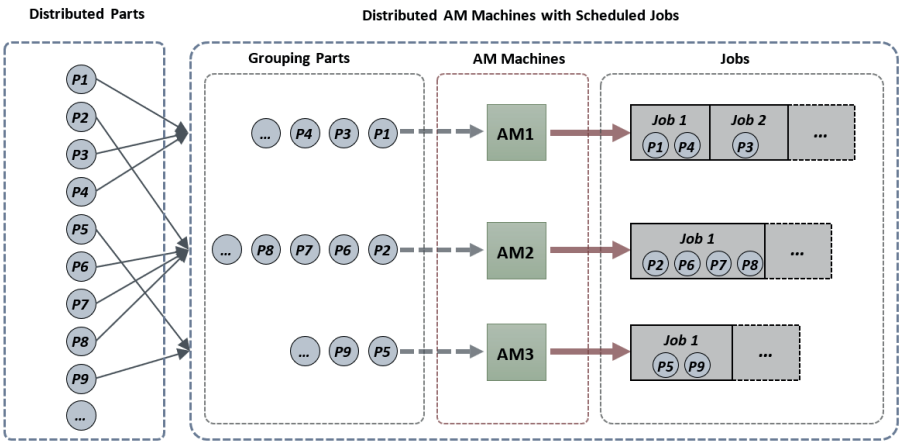

Fig. 2. A schematic representation of the multiple AM machine scheduling problem [1].

One can suppose that there is a two-stage decision making process. However, the parts are grouped as a job batch considering not only other parts in the same job, but also the specifications of the machine that job will be fabricated on. Therefore, these two questions are tightly interrelated to each other and the solution process cannot be divided into two consecutive stages. The problem must be handled through a holistic view.

Another complicated feature of this problem is that the processing times of jobs are dynamically calculated via a formula. That means the processing times are not known before the content of the job is not decided. For example, in a classical batch scheduling problem, the maximum processing time of a part in a batch determines the processing time of that batch. However, in a metal AM scheduling problem, the processing time of a job (or batch) is calculated via a formula (see Eq. (1)) considering the maximum height and total volume of the parts assigned to that job.

Each part ($i \in I$) has a width (w_i), length (l_i), height (h_i), area (a_i), volume (v_i), release date (r_i) and due date (d_i). Each machine ($m \in M$) has a maximum width (MW_m), length (ML_m), height (MH_m) and area (MA_m) supported by its tray or building platform. Machines also have other parameters, i.e. VT_m, HT_m, and SET_m. These

parameters are used for calculating job processing times and costs. VT_m is the time spent to form per unit volume of material. HT_m is the time spent for powder-layering (it is repeated for each layer based on the highest part produced in the job). SET_m is the set-up time needed for initialising and cleaning before/after each job. Eq. (1) is used to calculate the production time of a job ($j \in J$) on a machine (m).

$$PT_{mj} = SET_m \cdot Z_{mj} + VT_m \cdot \sum_{i \in I} v_i \cdot X_{mji} + HT_m \cdot \max_{i \in I}\{h_i \cdot X_{mji}\} \quad (1)$$

where X_{mji} and Z_{mj} are binary variables. X_{mji} is equal to 1 if part i is assigned to job j on machine m, otherwise it is 0. Z_{mj} is equal to 1 if job j on machine m is utilized; 0, otherwise. A job is considered to be utilized if at least one part is assigned to that job.

As seen in Eq. (1), PT_{mj} is the sum of three terms: (i) set-up time, (ii) material releasing time (based on total volume) and (iii) powder layering time (based on maximum height). This equation indicates that different combinations and allocations of same parts on to different machines yield different processing times and so completion times of parts. Therefore, grouping parts with similar heights may provide an advantage in reducing the processing time of a job.

The completion time of a job on a machine (CT_{mj}) can be stated as in Eq. (2).

$$CT_{mj} \geq ST_{mj} + PT_{mj} \quad \forall m \in M, j \in J. \quad (2)$$

where ST_{mj} is the start time of job j on machine m. A job can start when all parts in this job are ready to be built and no part can be removed until *all* parts in the job are completed. Therefore, the start time of a job (ST_{mj}) must be greater than or equal to the maximum of release dates in that job, i.e. $ST_{mj} \geq \max_{i \in I_{mj}}\{r_i\}$ where I_{mj} denotes the set of parts assigned to job j on machine m. Considering the basic assumption of processing one job at a time on a machine, it is necessary to start a job after the completion of a previous job on that machine ($ST_{mj} \geq CT_{m,j-1}$). Therefore, the start time of a job can be expressed as in Eq. (3), where $CT_{m0} = 0$.

$$ST_{mj} \geq \max\left\{CT_{m,j-1}, \max_{i \in I_{mj}}\{r_i\}\right\} \quad \forall m \in M, j > 1. \quad (3)$$

The completion time of a part (C_i) is equal to the completion time of job in which this part is assigned; $C_{i \in I_{mj}} = CT_{mj}$. Thus, the tardiness of a part (T_i) can simply be calculated as $T_i = \max\{0, C_i - d_i\}$. Thus, the objective function is to minimize the total tardiness $T = \sum_i T_i$.

A 2D nesting problem occurs to ensure a feasible allocation of parts into job batches. One can assume that it is enough to satisfy that the sum of part areas does not exceed the building area capacity of the machine's platform. However, there is a chance that this assumption can yield infeasible solutions when the parts are physically located on the machine platform. Therefore, a 2D nesting problem has also been combined with the machine scheduling problem in this research.

Basic assumptions of the problem are given as follows:

- The maximum capacity (width, length and height) of at least one machine is large enough to fabricate the largest part in terms of width, length and height.
- Part specifications are known and deterministic.
- Machine specifications are known and deterministic.
- Machines may have different capacity and specifications.
- No breakdowns or failures.
- Only one job can be processed on a machine at any time.
- All parts need to be assigned to a job exactly once.
- No parts can be added to a job after the job starts.
- A part can be removed from a job after all parts have been completed in the same job.
- All machines are available at the start of planning period.
- Building orientations of parts are known and constant.
- 2D nesting problem is considered to ensure that the allocations do not exceed machines' width and length.

Under these assumptions, the problem is to find the optimum allocation of parts to jobs on machines such that the total tardiness is minimized. Following section presents the proposed GA based approach with numerical examples.

4 Proposed Method

The problem studied here is neither a classical machine scheduling problem nor a nesting problem itself. Therefore, a sophisticated solution method is necessary to obtain efficient as well as high-quality solutions.

In this research, the GA approach proposed by Kucukkoc et al. [4] is modified to minimize total tardiness considering the 2D nesting constraints. The pseudocode of the proposed GA approach is given in Fig. 3.

```
GA
1    Generate initial population
2    Evaluate chromosomes in the population (considering 2D
     nesting constraints)
3    WHILE (no improvement in the last MaxItNoImp iterations)
4        Tournament selection
5        Genetic operators (Crossover & Mutation)
6        Evaluate newly generated chromosomes
7        Form new generation (replace the worst in the popula-
         tion)
8    ENDWHILE
9    Stop and report the best solution
```

Fig. 3. Pseudocode of the proposed GA approach.

The algorithm starts with generating random chromosomes to assure diversity. Fig. 3 presents the pseudocode of the proposed GA approach. The number of chromosomes in the population is constant. After generating the population, each chromosome in the population is evaluated using the procedure given in Fig. 4 considering the nesting constraints. Parents are selected using tournament selection (given in Fig. 5) and genetic operators are applied. The procedures used for crossover and mutation are given in Fig. 6 and Fig. 7, respectively. After crossover and mutation, the newly obtained individuals (children) are evaluated using the same decoding procedure and the new population is formed replacing the worst chromosomes with a better child (if any). Each chromosome is made up of part numbers (or IDs) generated with permutation coding. So that, each gene represents a part number and each part is represented on the chromosome only once. Therefore, the length of a chromosome equals the number of parts to be produced. If there are 8 parts, a sample chromosome could be `chrom={3,8,4,1,7,2,6,5}`. The order of parts on the chromosomes are used in the decoding procedure. Parts are selected one by one based on their sequence on the chromosome and allocated to jobs on machines based on the decoding procedure provided in Fig. 4 (where `AP` denotes the list of parts not assigned and `nm` is the number of machines).

Decoding Procedure

```
1    Add all parts into set AP in the order that they appear on
     the chromosome
2    Set j ← 1 //job index
3    WHILE (AP ≠ ∅)
4      FOR (m = 1 TO nm STEP 1) //start from the first machine
5        totArea ← 0, I_mj ← ∅
6        FOREACH (i in AP) //try each part
7          IF (totArea + a_i ≤ MA_m and h_i ≤ MH_m and w_i ≤ MW_m and
           l_i ≤ ML_m)
8            IF (totArea = 0 or Nesting(i, I_mj) = true)
9              Add part i to I_mj
10             totArea ← totArea + a_i
11             Remove part i from AP
12           ENDIF
13         ENDIF
14       ENDFOREACH
15       j ← j + 1
16     ENDFOR
17   ENDWHILE
18   return
```

Fig. 4. Pseudocode of the decoding procedure.

In the decoding procedure, nesting constraints are satisfied via an external function, called `Nesting()`, for which the source code can be retrieved from GitHub [11]. This function gets a machine ID and a list of parts as parameter and returns true if they fit on the machine tray with no exceedance. The algorithm starts with the first machine and first job. The first part on the chromosome is selected and checked if it fits on the tray. If the part's width, length, height and area are smaller than or equal to the machine's width, length, height and area, the first phase of the control process is completed. In the second phase of the control process, the machine ID and part's data is sent to the `Nesting()` function together with existing parts list in the same job on the same machine. If the returned result is true, the part is assigned to the current job and the `totArea` is increased by a_i. If the result is false, the next part is checked following the same procedure. When no more part can be allocated to a job, the machine ID is altered and the unallocated parts are tried to be assigned after a two-stage feasibility control process. When all the machines are full, new jobs are opened and the assignment process continues starting from the first machine again. This cycle continues until all parts have been allocated. As seen from this procedure, a two-stage control process is utilized to check the assignment feasibility of a part to a job on a machine and the nesting condition is checked if the first stage is completed successfully. This is because `Nesting()` function has a time consuming procedure and it is called only when the first phase of the control is completed successfully. So that any unnecessary nesting efforts are avoided.

The parents for genetic operators are selected using a tournament selection procedure given in Fig. 5. To determine two parents, the procedure is applied twice and the winners are designated as parents. The tournament size (`tourSize`) is determined as `Ceil(popSize/6)`, where `Ceil(X)` returns the smallest integral value that is greater than or equal to `X`. So that the diversity is ensured and chromosomes with better fitness values have more chance for reproduction. However, all individuals have a chance to be selected.

Selection (Tournament)

```
1    Set min ← MAX_Value, winner ← ∅, tourSize ← Ceil(popSize/6)
2    FOR (t = 1 TO tourSize STEP 1)
3      Choose a random chromosome (p) from the population
4      IF (Fitness(p) < min)
5        Set winner ← p
6      ENDIF
7    ENDFOR
8    return
```

Fig. 5. The procedure used for tournament selection.

Winners of the tournament selection (`parent1` and `parent2`) undergo crossover and mutation, respectively. Crossover helps mostly better chromosomes generate new

individuals and form next generations. It is applied via determining a random cut point (`cp`) and systematically combining the genes of the two parents referencing that cut point (see Fig. 6). The head of `child1` is retrieved from the first part of `parent1` (from the first gene to `cp`). The remaining genes of `child1` is completed based on the sequence of missing genes after `cp` on `parent2`. Similarly, the head of `child2` is the head of `parent2` (from the first gene to `cp`) and the remaining part (`tail2`) of `child2` is completed based on the order of missing genes after `cp` on `parent1`. So that, one crossover is completed. This is repeated several times based on a parameter called `crossover rate` whose value is determined by the user.

Crossover

```
1   cp ← [1, chromSize] //Determine a random cut point (cp)
2   Initialise child1 and child2; child1 ← ∅, child2 ← ∅
3   head1 ← parent1[1, cp]; head2 ← parent2[1, cp]
4   temp1 ← parent1[cp + 1, chromSize] + parent1[1, cp]
5   temp2 ← parent2[cp + 1, chromSize] + parent2[1, cp]
6   Set tail1 ← ∅, tail2 ← ∅
7   FOREACH (i in temp2) //Build tail1
8     IF (i ∉ head1)
9       Add part i to tail1
10    ENDIF
11  ENDFOREACH
12  FOREACH (i in temp1) //Build tail2
13    IF (i ∉ head2)
14      Add part i to tail2
15    ENDIF
16  ENDFOREACH
17  child1 ← head1 + tail1, child2 ← head2 + tail2
18  return
```

Fig. 6. The procedure used for crossover.

Mutation is another important genetic operator. It helps algorithm scan different areas of the search space and prevents algorithm stuck in local optima. Fig. 7 shows the procedure used for mutation. A parent is selected from the population via tournament selection and either `swap` or `insert` is applied based on the value (between [0,1]) of a random variable, i.e. `rand`. The two randomly determined genes are swapped and a mutant is constituted if the random variable is lower than 0.5. If not, a randomly determined gene is moved to another randomly determined location to obtain a `mutant`.

Mutation rate controls how many times mutation will be applied on a newly selected parent.

```
Mutation
    rand ← Random[0,1] //to determine swap or insert
    r1 ← Random[1, chromSize] //determine a random location r1
    r2 ← Random[1, chromSize] //determine a random location r2
    WHILE (r1 = r2)
      r2 ← Random[1, chromSize]
    ENDWILE
    IF (rand < 0.5) //swap operation
      temp ← parent[r1]
      parent[r1] ← parent[r2]
      parent[r2]] ← temp
    ENDIF
    IF (rand ≥ 0.5) //insert operation
      Move part at r1 to its new location r2 on parent
    ENDIF
    return
```

Fig. 7. The procedure used for mutation.

New generation is formed replacing the worst chromosomes in the population with the best individuals (children) obtained from genetic operators. In this process, it is very important to avoid duplication of chromosomes. Otherwise, a couple of iterations later the population may be just a multiple copy of the same chromosome.

The algorithm runs until there is no improvement in a predefined number of iterations and the best solution is reported.

5 Tests and Results

The proposed GA approach has been coded in JAVA and run on Intel® Core™ i7-6700HQ CPU @2.60 GHz with 16 GB of RAM to solve the test problems given in Table 1. Number of parts (*nbParts*), number of machines (*nbMachines*), range of parts, and machines used to fabricate parts are provided for each test instance. For example, I6 is constituted of 14 parts (i.e. P15-P28 in part dataset) and three SLM machines (two of which are M1 and the other one is of M2). Test problems have been organized in ascending order of their complexity. The problem complexity increases when the number of parts and the number of machines get larger. Machine park has been differentiated to obtain a more diversified problem set. Details of SLM machine specifications

are obtained from Kucukkoc [1] and provided in Table 2. Part dataset is also provided in Table A1 (see Appendix).

The population size, crossover rate and mutation rate are considered to be 30, 0.6 and 0.1, respectively. The algorithm was terminated when there is no improvement within 2500 iterations for test instances I1-I6 and 5000 iterations for test instances I7-I20. The values of these parameters have been determined through some preliminary tests considering the problem size [7].

Table 1. Data on test instances.

Test Instance	nbParts	nbMachines	Range of Parts	Machines
I1	12	2	P1-P12	M1[1], M2[1]
I2	12	2	P13-P24	M1[1], M2[1]
I3	14	2	P1-P14	M1[1], M2[1]
I4	14	2	P15-P28	M1[1], M2[1]
I5	14	3	P1-P14	M1[1], M2[2]
I6	14	3	P15-P28	M1[2], M2[1]
I7	18	2	P1-P18	M1[1], M2[1]
I8	18	2	P11-P28	M1[1], M2[1]
I9	18	2	P15-P32	M1[1], M2[1]
I10	18	3	P19-P36	M1[2], M2[1]
I11	24	3	P1-P24	M1[2], M2[1]
I12	24	3	P1-P24	M1[1], M2[2]
I13	24	4	P17-P40	M1[2], M2[2]
I14	24	5	P17-P40	M1[3], M2[2]
I15	30	5	P1-P30	M1[3], M2[2]
I16	30	6	P1-P30	M1[3], M2[3]
I17	30	7	P11-P40	M1[4], M2[3]
I18	30	8	P11-P40	M1[4], M2[4]
I19	40	11	P1-P40	M1[6], M2[5]
I20	40	12	P1-P40	M1[6], M2[6]

Table 2. Machine specifications.

Machine ID	Height (cm)	Width (cm)	Length (cm)	Area (cm^2)	Set-up Time (hr)	HT (hour/cm)	VT (hour/cm^3)
M1	32.5	25	25	625	2.00	1	0.030864
M2	32.5	25	25	625	1.00	1	0.030864

The results of the experimental tests have been reported in Table 3. The column *nbJobs* indicates the total number of jobs utilized on machines. While the ultimate goal of the GA is to minimize *total tardiness*; *maximum tardiness* and *the number of late parts* are also reported as additional performance indicators. Moreover, the time consumed to

solve each problem has been reported in seconds (s) for the comparison purposes in future researches.

The GA algorithm finds reasonable solutions within short CPU times. The CPU time requirement increases with the increase in the number of parts and so the problem complexity. This is because of the exponential increase in the search space. Each problem has been solved three consecutive times and the best results are reported.

When the results are investigated, some problems have no tardiness. See, for example, I1, I5-I7 and I10. That means no part is late in these cases. In I3 and I5, the same parts (i.e. P1-P14) are scheduled with a different machine park. For I3, there is only one machine in each type (M1 and M2). So, this problem is solved with a total of two machines. However, for I5, there are three machines in total (two machines of type M2 and one M1) which yields a better fitness value (0 instead of 18.57) as expected. The maximum of objective value was observed for I8 with a total tardiness of 335.08 hr.

Table 3. Results of the experimental tests.

Test Instance	nbJobs	Maximum Tardiness (hr)	Number of Late Parts	Total Tardiness (hr)	CPU(s)
I1	5	0	0	0	31
I2	6	57.89	2	66.43	39
I3	6	10.35	2	18.57	62
I4	6	56.58	3	98.55	46
I5	5	0	0	0	66
I6	6	0	0	0	52
I7	8	0	0	0	142
I8	7	135.44	5	335.08	118
I9	8	97.12	7	308.61	89
I10	9	0	0	0	100
I11	9	10.22	1	10.22	183
I12	9	7.54	1	7.54	172
I13	9	114.30	3	213.50	175
I14	10	34.84	2	36.92	231
I15	12	28.19	2	38.36	432
I16	11	26.21	3	58.16	321
I17	13	110.64	5	174.66	225
I18	12	94.06	3	139.80	339
I19	15	62.46	6	148.56	386
I20	15	76.52	3	152.44	586

A part of the convergence graph of the proposed GA approach is given in Fig. 8 for I12 where total tardiness is ‘7.54’. As seen from the graph, the best fitness value in the initial population was over 1000 hr of total tardiness. GA produces efficient schedules which gradually decreases total tardiness to ‘7.54’ in the first 500 iterations.

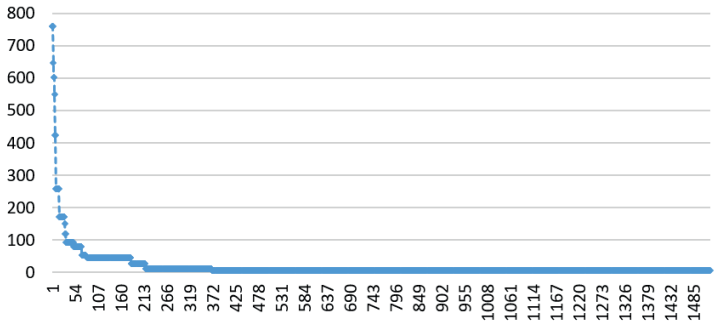

Fig. 8. Convergence of the proposed algorithm (the first section)

The detailed nesting result of the best solution for I12 is also provided in Fig. 9. It is worthy to note here that the nesting function is used just to make sure that the assigned parts to a job do not exceed the dimensions of the tray, not to maximize the utilization of the trays. This is because minimization of the *nbJobs* does not mean the minimization of the total tardiness as contextualized in previous sections.

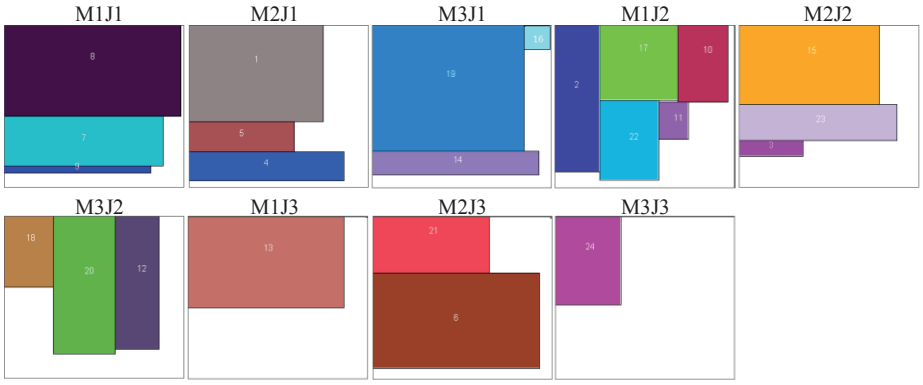

Fig. 9. Allocation of parts to jobs.

6 Conclusions and Future Research

This paper proposed a GA approach for scheduling metal additive manufacturing machines to minimize total tardiness considering 2D nesting constraints in a multiple unrelated parallel machine environment. The proposed method employs a nesting function which ensures that the parts assigned to a job on a machine do not exceed tray capacity (in terms of width and length) as well as height. The production time of a job is calculated via a function based on the content of the job, i.e. the maximum height and total volume of parts assigned to that job. Pseudocodes of GA mechanisms have been provided and test problems have been solved. Test data is given in details to provide comparable data in future researches. The results reported exhibits the promising solution

building capacity and convergence of the proposed approach. However, as the problem is new and there is no comparable result reported in the literature, the performance of the proposed GA has not been compared to another method.

In future studies, new metaheuristics (e.g. ant colony, tabu search, bee colony etc.) can be developed to solve the test instances provided in this paper and results can be compared to that of GA reported in this paper. The capacity of the proposed GA can also be improved with some problem specific genetic operators. Furthermore, fabrication of irregular shaped parts on multiple SLM machines can be considered as an original research topic for future works.

A Genetic Algorithm for Flexible Job Shop Scheduling Problem with Scarce Cross Trained Setup Operators*

Dolapo Obimuyiwa and Fantahun Defersha

School of Engineering, University of Guelph, 50 Stone Road East, Guelph, Ontario, Canada, N1G 2W1

Abstract. Many researchers developed algorithms for a dual-resource constrained flexible job shop (DRC-FJSP) where both machines and workers need to be simultaneously scheduled. In those models and algorithms in the literature, the authors assumed that workers are machine operators responsible for performing the production process steps from the beginning to the end of the operation. However, because of increased automation and the adoption of numerically controlled machines, workers become machine tenders and should not be bottleneck and constraining resources. On the other hand, skilled setup operators remain being constraining limited resources in industries. Unlike machine tenders, a setup operator can leave the machine once setup is completed and take on another setup operation on another machine. In this paper, for the first time, we develop a genetic algorithm for a new DRC-FJSP where setup operators and machine tools are constraining resources. Numerical examples of varying problem sizes are presented to show the performance of the algorithm.

Keywords: Flexible Job-shop Scheduling; Dual Resource Constrained; Scarce Setup Operators; Detached setup; Genetic Algorithm.

1 Introduction

Flexible job-shop scheduling problem (FJSSP) is an expansion of the job shop scheduling problem (JSSP), which is one of the combinatorial optimization problems considered to be NP-hard [5, 2, 3]. The consideration of machines and the human resource component in the scheduling environment is known as a Double-Resource, or Dual-Resource constrained (DRC) system. Systems centered around human resources are viewed across literature under DRC, where the degree of versatility and workforce assignment could affect the system's performance [6]. Dual-resource constrained systems are more complex than their counterparts, single resource costrined (SRC), and they pose extra challenges that need to be addressed during resource scheduling [14]. The primary aim of human-resource

* Corresponding Author: F. Defersha, Email: fdefersh@uoguelph.ca, Home Page: www.defersha.ca

scheduling in DRC systems is to have the right amount of eligible people to perform the required task at the right time. Human operators that are not cross-trained cannot address situations where there are unexpected work-orders and unbalanced workloads [9, 8]. While the DRC systems' efficiency increases with workers' versatility [1]; however, according to [7], having a workforce system that is fully cross-trained may not be attainable due to the high cost of training. Previous studies have been scheduling workers as operators whose duty is to operate the machines with no experience or training on machine setups. It is assumed that this category of machine operators can be acquired at low cost (i.e., cheap labor that can be hired and fired at will). Also, the machine operators must stay and tend the assigned machines for the entire duration of work (i.e., they are not free to move in between machine operations).

However, in setting up complex and heavy-duty machines, there's a need to be prudent in hiring highly skilled personnel who are cross-trained in machine setups, which comes at a great cost. This category of people is considered costly labor, which might not seem reasonable to hire and fire at will due to their scarcity and cost of hiring. Furthermore, these setup-operators are free to move in between setup operations (i.e., they can move after completing initial setups to subsequent ones) and are not required to stay for the entire duration of the work schedule. Hence, the need for the effective optimization of these limited resources should not be neglected. To this end, in this paper, we propose a new DRC-FJSSP problem that incorporates a limited number of cross-trained skilled setup-operators. For more information on the DRC systems, see other recent publications by [15], [11], [13], and the recent survey by [4]. The rest of this paper is organized as follows: Section 2 presents the problem to be addressed, its assumptions, and the corresponding notations. The proposed genetic algorithm (GA) and its components are presented in Section 3. Numerical examples are presented in Section 4 to illustrate the problem addressed in this paper and show the computational efficiency of the proposed algorithm. Finally, conclusions are given in Section 5.

2 Problem Statement, Assumptions and Notations

This section presents the problem to be addressed, its assumptions, and the corresponding notations. Generally, SRC-FJSSP consists of two major subproblems: sequencing of operations and the selection of machines. In contrast, DRC-FJSSP consists of the two major sub-problems of an SRC-FJSSP, with the addition of one more problem referred to as the selection of workers. Therefore, the DRC problem in this paper consists of three (3) subproblems, namely: (1) the selection of a machine for each operation, (2) the sequence of operations on selected machines, and (3) the selection of an eligible setup operator for setting up a machine. For this paper, the DRC-FJSSP in the presence of a scarce number of skilled cross-trained setup operators (SSO) will be hereafter denoted as "DRC-FJSSP-SSO."

2.1 Problem Statement

Consider a job-shop consisting of M-machines where certain machines m are similar or have some common functionalities. Also, the schedule of the system includes a set of J-independent jobs j with a number of operations O_j in a predefined arrangement where each operation o of job j can be processed on a set of alternative and eligible machines. The total time spent by an operation o of job j on machine m is defined as the setup-time denoted by $(S_{o,j,m})$ and the processing time (batch size B_j multiplied by unit processing time $T_{o,j,m}$). The setup of this operation o can be started once the assigned machine completes its previous operation, and an eligible setup operator is available. Furthermore, there are N setup-operators where each setup operator n (where $n = 1, \ \ldots, \ N$) is trained to perform setup of operation o on a given set of machines m. Hence, as seen in figure 1, the problem is the assignment of each operation to one of its alternative and qualified machines, determine the sequence and starting time of the operations on each machine and the eligible setup-operator for each machine. Figure 1 is a case of four jobs, three machines (i.e., partial flexibility), two setup-operators, and the setup-operators are trained to set up some of the machines (i.e., partial flexibility). For example, operation 1 of job 4 can be set up on both machine 2 and machine 3 by either setup-operator 1 or setup-operator 2, and operation 2 of job 4 can be setup on machine 1 by setup-operator 1 only, and on machine 3 by both setup-operator 1 and 2. Note that in a shop system, a machine is said to be partially flexible when all job-operations cannot be carried out on all the machine, and a setup-operator is also said to be partially flexible when he/she cannot carry out setup-operations on all machines (i.e., setup-operator 2).

2.2 Assumptions

The following assumptions were made for the model in addressing the problem in this paper:

(i) A machine can process at most a single operation at a given period of time (i.e., machine-capacity constraint)
(ii) Once the processing of an operation begins, it cannot be interrupted until it is done (i.e., Pre-emption not allowed).
(iii) Each operation of a job can be assigned to at most a single machine and a single eligible setup-operator at a given period of time (i.e., resource-constraint)
(iv) Modification is not allowed to the predetermined sequence of the operations for each job (i.e., precedence-constraint)
(v) Each setup-operation can be carried out by only one setup-operator (i.e., setup-operator constraint)
(vi) The nature of all setups are in detached mode (i.e., setup of a particular operation can begin before its arrival on the assigned machine)
(vii) The setup-operator's movement time is negligible.

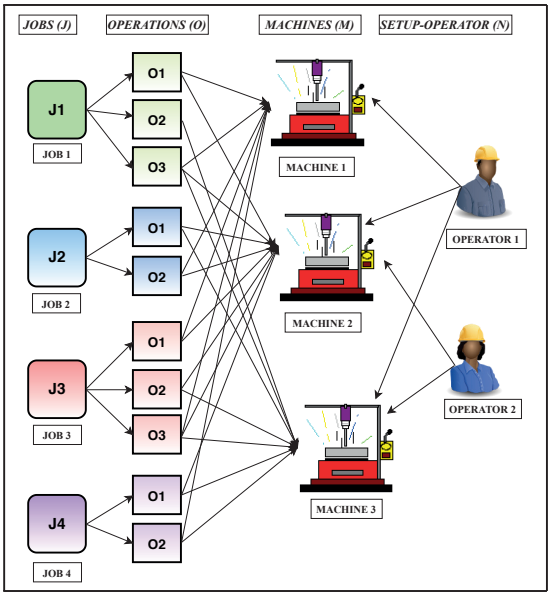

Fig. 1: A basic example of the DRC-FJSSP-SSO.

2.3 Necessary Notations

The following notations were used in the solution procedure in this paper. Additional notation and MILP formulation can be found in [10].

Indexes and Parameters:

m	An index for machines, where $m = 1, 2, 3, \ldots, M$, where M is the number of machine;
r	An index for machine run, where a run is defined as an processing of an operation by a machine;
n	An index of setup operator, where $n = 1, 2, 3, \ldots, N$, where N is the nubber of setup operators such that $N \ll M$.
k	An index of setup operation performed by an operator
$P_{o,j,m}$	A binary variable which takes the value 1 if operation o of job j can be executed on machine m, or 0 otherwise;
$\Theta_{n,m}$	A binary variable which takes the value 1 if setup operator n is eligible to perform setup on machine m, 0 otherwise
Ω	Large positive number.

Decision Variables:

$\widehat{C}_{r,m}$	Completion time of the r^{th} run of machine m;
$s_{k,n}$	Completion time of the k^{th} setup of setup-operator n; and
C_{max}	Completion time of all jobs ($Makespan$);

3 Components of the Proposed GA

3.1 Solution Representation

Solution representation in GA is a critical step in the algorithm's implementation. The solution representation technique used in this paper follows a similar concept used in [5]. However, as seen in figure 2(a), the triplet-gene solution encoding scheme used in [5] was improved into a new encoding scheme as seen in figure 2(b). Unlike the SRC-FJSSP where the machine is the only resource considered in the scheduling problem, an additional resource constraint is added to the SRC-FJSSP to make it DRC-FJSSP. Due to the addition of an extra constraint (i.e., setup-operators), the triplet(j, o, m) gene of a SRC-FJSSP is now augmented into a quadruple(j, o, m, n) gene for the DRC-FJSSP-SSO as shown in Figure 2(b), where the o^{th} operation of job j that is assigned to the eligible machine m is setup by setup-operator n. Furthermore, for any given j, if o ¡ o', a gene with a value (j, o, m, n) must appears earlier in the sequence before the gene with value (j, o', m', n) irrespective of the values of m and m'. For a given gene value (j, o, m, n), the value of the indices should satisfy the condition set by eligibility indicator data, i.e., $P_{o,j,m} = 1$ and $\Theta_{n,m} = 1$.

3.2 Evaluation

Based on the assignment and sequencing information obtained from a solution string, the resulting starting and completion times of jobs and, hence the makespan of the schedule can be determined. The makespan is used to evaluate how fit the individual is. In calculating the makespan, we take into account the following: (1) the machine setup time by setup-operators, (2) the detached nature of setup, and (3) the cross-training ability of setup-operators. The procedure for this calculation is outlined below:

Step 1. Set $l = 1$

Step 2. For the particular solution-string under consideration, set the values of indices j, o, m and n as secured from gene at location l.

Step 3. Calculate the completion times $s_{k,n}$ and $\widehat{C}_{r,m}$

- If operation o of job j is the first operation assigned to run r of machine m and the first setup-operation k to be performed by setup-operator (n) on the same machine (i.e., $r = 1$, $o = 1$, $k = 1$) then:
  $s_{k,n} = S_{o,j,m}$ and $\widehat{C}_{r,m} = S_{o,j,m} + B_j \cdot T_{o,j,m}$
- If (a) operation $o > 1$ of job j is the operation assigned to run r of machine m and first setup-operation k to be performed by setup-operator (n) on the same machine (i.e., $r = 1$, $o > 1$, $k = 1$) and (b) operation $o - 1$ was assigned to run r' on machine m', then:
  $s_{k,n} = S_{o,j,m}$ and $\widehat{C}_{r,m} = \max\{S_{o,j,m};\quad \widehat{C}_{r',m'}\} + B_j \cdot T_{o,j,m}$.

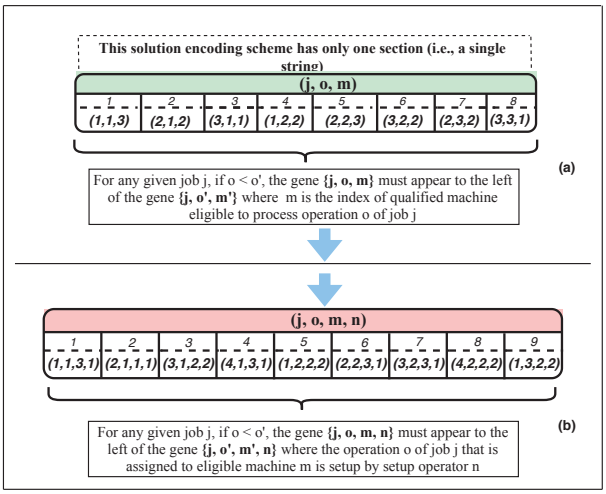

Fig. 2: Solution encoding schemes for (a) SRC-FJSSP and (b) DRC-FJSSP-SSO

- If operation o of job j is the operation to be processed on run $r > 1$ machine m and the setup-operation k is the first to be performed by setup-operator (n) machine m (i.e., $r > 1$, $o = 1$, $k = 1$) then:
  $s_{k,n} = \widehat{C}_{r-1,m} + S_{o,j,m}$ and $\widehat{C}_{r,m} = s_{k,n} + B_j \cdot T_{o,j,m}$
- If (a) operation $o > 1$ of job j is the operation to be processed on run $r > 1$ and the setup-operation k is the first to be performed by setup-operator (n) machine m (i.e., $r > 1$, $o > 1$, $k = 1$) and (b) operation $o - 1$ was assigned to run r' on machine m', then:
  $s_{k,n} = \widehat{C}_{r-1,m} + S_{o,j,m}$. and $\widehat{C}_{r,m} = \max\{s_{k,n}; \quad \widehat{C}_{r',m'}\} + B_j \times T_{o,j,m}$.
- If operation o of job j is the first operation assigned to run r on machine m and k is not the first setup to be performed by setup-operator (n) (i.e., $r = 1$, $o = 1$, $k > 1$) then:
  $s_{k,n} = s_{k-1,n} + S_{o,j,m}$. and $\widehat{C}_{r,m} = s_{k,n} + B_j \cdot T_{o,j,m}$
- If (a) operation o of job j is the first operation to be processed and k is not the first setup to be performed by setup-operator (n) on machine m (i.e., $r = 1$, $o = 1$, $k > 1$) and (b) operation $o - 1$ was assigned to run r' on machine m', then:
  $s_{k,n} = s_{k-1,n} + S_{o,j,m}$. and $\widehat{C}_{r,m} = \max\{s_{k,n}; \quad \widehat{C}_{r',m'}\} + B_j \times T_{o,j,m}$.
- If k is not the first setup to be performed by setup-operator (n) on machine m for operation $o = 1$ of job j (i.e., $k > 1$, $r > 1$, $o = 1$) then:
  $s_{k,n} = \max\{s_{k-1,n}; \quad \widehat{C}_{r-1,m}\} + S_{o,j,m}$ and
  $\widehat{C}_{r,m} = s_{k,n} + B_j \cdot T_{o,j,m}$
- If (a) k is not the first setup to be performed by setup-operator (n) on machine m for operation o of job j (i.e., $r = 1$, $o > 1$,

$k > 1$) and (b) operation $o-1$ was assigned to run r' on machine m', then:
$s_{k,n} = \max\{s_{k-1,n};\quad \widehat{C}_{r-1,m}\} + S_{o,j,m}$ and
$\widehat{C}_{r,m} = \max\{s_{k,n};\quad \widehat{C}_{r',m'}\} + B_j \times T_{o,j,m}$.

Step 4. If l is less than the total number of genes of the chromosome, increase its value by 1 and go to Step 2; otherwise go to Step 5

Step 5. Calculate the makespan of the schedule as $c_{max} = \max\ \widehat{C}_{r,m};\ \forall(r,m)\}$ and set the fitness of the solution to c_{max}.

3.3 Genetic Operators

GAs uses genetic operators to evolve a population of solutions towards a promising region of the search space. Generally, these operators are classified as selection, crossover, and mutation operators. The selection operator chooses the chromosomes for reproduction. In the proposed GA, a k-way tournament (KWT) and a roulette wheel selection (RWS) method was used to select individuals. The KWT selection method is used to first select k individuals randomly. Then, the individual with the highest fitness (smallest makespan) is declared the winner. This process of selection is repeated with replacement until the number of the new set of individuals is the same as the population size. In an RWS, the wheel is divided into sections according to the fitness of each solution-string and is rolled n-number of times where n is the same as the population size. In each spin, the solution-strings with the most extensive section on the wheel have a higher probability of been selected based on a higher fitness value. Once the individuals have been selected for reproduction, crossover and mutation operators are applied to the offspring. These operators can be classified as assignment and sequencing operators. The assignment operator only alters the assignment property of the parent chromosomes, while sequencing operators only alters the sequence of the operations in the parent chromosomes. The assignment operators used in this paper are (1) machine-operation assignment crossover, (2) machine-operation assignment mutation, (3) single-point crossover, and (4) setup-operator assignment mutation.

Assignment crossover operator is applied with probability α_1, and it produces offsprings by exchanging the assignment of arbitrarily chosen operations between two parents, as shown in figure 3. The assignment mutation operator is applied with probability α_2. It alters the assignment of a few operations of a given chromosome. In a single-point crossover, a point is arbitrarily selected on both parent 1 and parent 2, and labeled as the crossover point. The arbitrarily selected point is chosen with a probability of α_3, and all the genetic information beyond the selected point is exchanged between the parent-strings to produce new offsprings. Setup-operator mutation is applied with probability α_4 on the randomly selected solution-string. As seen in Figure 4, it alters the setup-operator assignment of the solution-string by assigning the setup-operator to an alternative machine that he/she is qualified to setup. The sequencing operators used in this paper are (1) job-operation sequence-order crossover and

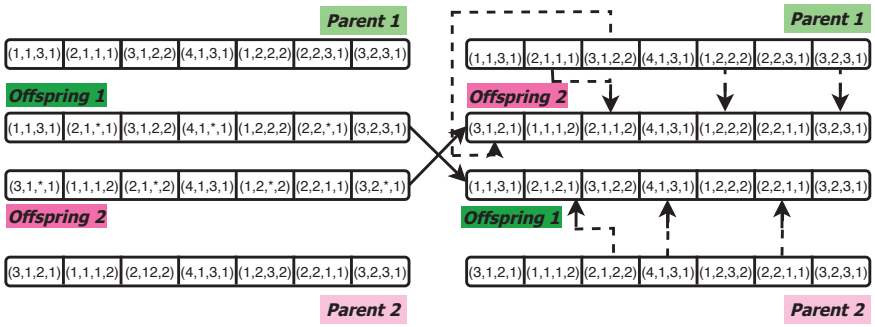

Fig. 3: Machine-operation assignment crossover.

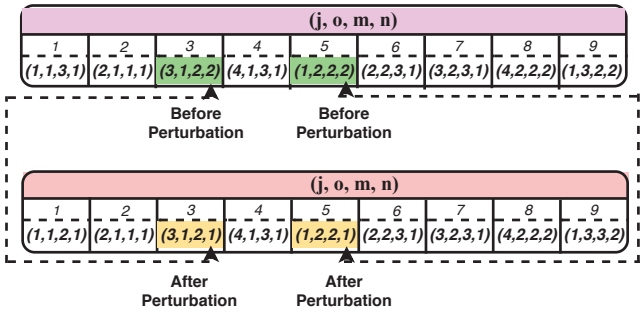

Fig. 4: Setup-operator assignment mutation.

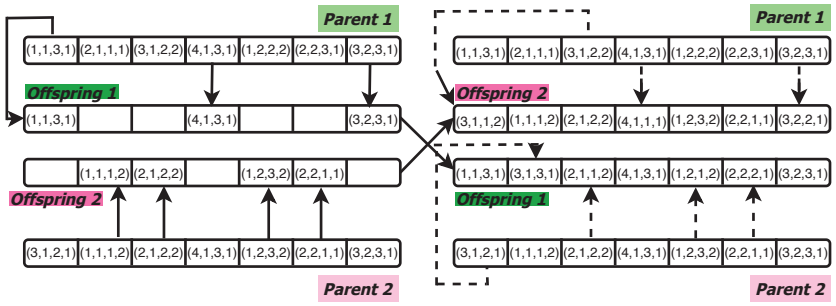

Fig. 5: Job-operation sequence-order crossover.

(2) operation sequence-swap mutation. With probability α_5, the job-operation sequence-order crossover operator is applied by randomly selecting one operation each from the parent chromosomes, copies all the operations of the job to which the selected operation belongs into the corresponding offsprings as illustrated in figure 5. It proceeds by completing the new offspring with the remaining operations in the same pattern of the second parent while maintaining the as-

signment structure of the operations in the first parent. This operator respects the precedence constraints among operations of the same job and ensuring it is not violated. The operation sequence-swap mutation operator is applied with a probability of α_6 on the solution-string in such a way that the position of the selected operation is swapped with another while ensuring that the precedence constraint is enforced.

4 Numerical Examples

In this section, we present an example problem to illustrate the features of the proposed model and the computational performance of the developed GA. A problem instance consisting of five machines, twelve jobs, and three setup-operators is considered. The batch size of each job is given in Table 1. This table contains, the number of operations in each job, the possible alternative machine routes for each operation, the eligible setup-operators for the machine, and the corresponding unit processing times and setup times. This example problem was solved using the Branch-and-Cut (BC) algorithm of ILOG CPLEX solver and the proposed GA for two different scenarios. In the first scenario, it is assumed that both the machines and the setup-operators are partially flexible. In contrast, in the second case, it is considered that only the setup-operators are flexible.

4.1 Solution Illustration

The developed GA was coded in C++ using Microsoft Visual Studio 2017. Both the ILOG CPLEX solver and the developed GA were implemented on a 64-bit operating system, 3.5 GHz Intel (R), 16GB RAM computer. The Gantt charts of the resulting schedules, as solved by the developed GA for the machines, is given in Figure 6, and the setup-operators is given in Figure 7. From Figure 8, it can be concluded that the developed GA ($makespan = 1605.0mins$) outperformed the Branch-and-Cut algorithm of the CPLEX solver ($makespan = 1927.5mins$) for both partial and total flexibility scenario ($GA - makespan = 1605.0mins, CPLEX - makespan = 2065.0mins$). In Figure 6, the detached nature of setup can be observed between operation 2 and 3 of job $j = 8$. It can be seen that the setup of operation 3 of job 8 can begin before the completion of operation 2 of job 8. The detached nature of setup also helps to reduce the idle or waiting time of setup-operators between consecutive machine setups as the setup-operator does not have to wait for the arrival of the previous operation of the job to begin setup for the next operation. For instance, setup-operator $n = 3$ would be able begin the setup of operation $o = 3$ of job $j = 8$ immediately after his last setup of operation $o = 2$ of job $j = 3$ at 367.5 due to the detached nature of setup, otherwise, the setup-operator would have to wait until operation $o = 2$ of job $j = 8$ is completed at 563.0 which would increase the potential idle-time by 35%. Furthermore, since there was no change in the makespan value for the two flexibility scenarios when solving with GA, it may be reasonable to say that for more work and cost-effectiveness, setup-operators can be trained on

some group of machines at a particular workstation than on all the machines in the entire shop system. This would also reduce the movement of setup-operators from one setup operation to another, resulting in a more cost effective and leaner manufacturing environment.

4.2 Algorithm Performance

Larger problem instances were developed to evaluate the performance of the genetic algorithm and the behavior of the algorithm to changes in genetic parameters. The case examples used in this study were generated and solved with different genetic problem-parameters for 10 test runs based on the provided procedures in [12] and in other GA published in the literature. Table 2 describes the general features of the case-examples, such as the problem instances, the total number of jobs, operations, machines, setup-operators, and alternative routes. The problem sizes used in this study are much larger than most of the ones used in literature. Figure 9 shows how the algorithm converges during iterations and how it responds to the tuning of genetic parameters for problems 3, 4, 5, and 6 after ten experimental runs. Problems 3 and 4 are considered as medium-sized problems, while problems 5 and 6 are regarded as large-size problems based on the total computational cost required during the iterations by the genetic algorithm. The genetic algorithm can converge during its iteration through a large generation in less computational time for medium-size problems while it takes more computational time to converge and progress from a certain number of generation to another in large-size problems.

5 Conclusions and Future Research

In this paper, we considered a DRC system that incorporates an additional resource of scarce cross-trained setup-operators with the detached nature of machine setups. The BC algorithm of the ILOG CPLEX solver and the proposed

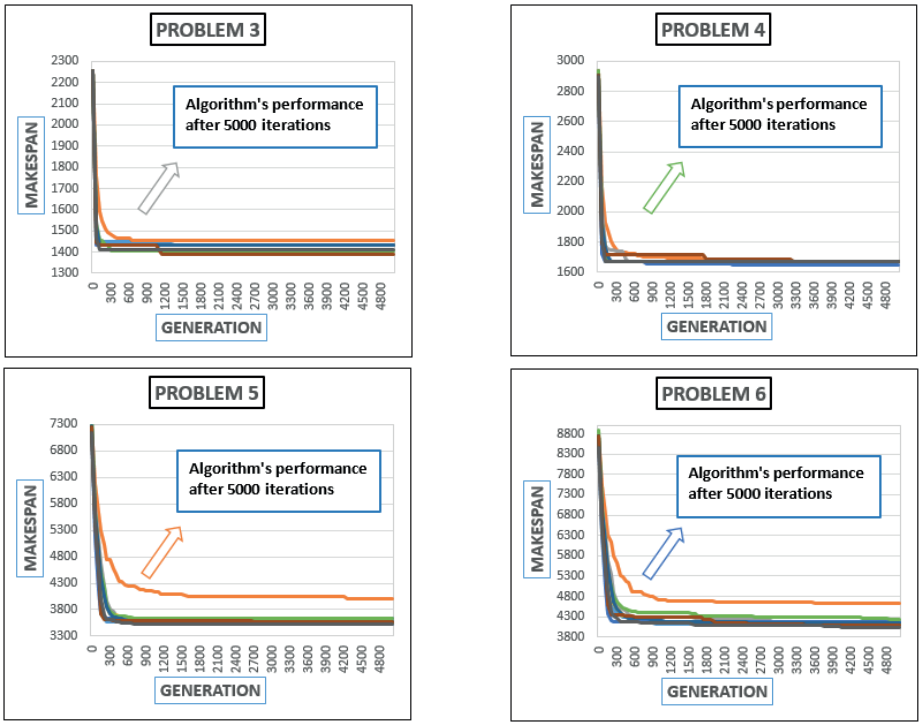

Fig. 9: Convergence behaviour of the GA for larger problem set over 10 runs.

GA was used in addressing an example problem. The results showed that the developed GA outperformed the BC algorithm both in the quality of solutions and the required computational cost. The performance from the GA further amplifies the dominance of metaheuristics approach to solving complex problems with less computing cost, and it also provides a good and promising foundation for further studies in limited cross-trained human-resource DRC systems. In our future research, we plan to extend the model and the solution procedure to consider multiple objectives such as machine workload-balancing, due dates, and other factors such as machine release dates, sequence-dependency setup times, and transportation time of setup-operators between setups.

Abstract. The present study addresses the personnel assignment and scheduling problems through the multiskilling flexibility strategy with the aim of reducing the negative impacts on a company's cost structure that come as a result of demand uncertainty. The personnel assignment matter is handled using the chaining approach and it is evaluated whether a multiskilled workforce that minimizes the expected costs associated with training and under/overstaffing can be planned while taking into account demand uncertainty and using the k-chaining policy for a days-off scheduling problem. Until now, literature's main focus has been 2-chaining policies, where every multiskilled employee is at most trained in two departments, i.e., k =2. Hence, this research intents to determine scenarios where a k-chaining policy with k≥2 offers more cost-effective multiskilling structures than a 2-chaining one. Initially, a deterministic mixed-integer linear optimization model is developed and then modified into a two-stage stochastic optimization model in order to add demand uncertainty. Such methodology is subsequently applied to a Chilean retail store where a Monte Carlo simulation is used to generate different daily demand scenarios. The results obtained suggest that with high levels of demand variability k-chaining policies seem favorable. Nonetheless, none of the employees evaluated were able to work in more than three departments, which leads to the conclusion that it does not appear to be advantageous to implement excessive flexibility levels.

Keywords: Personnel scheduling, Multiskilling, Chaining, Labor flexibility, Retail.

1 Introduction

An adequate personnel scheduling strategy is not only essential to a company in terms of securing a competitive advantage and thus acquiring means to outperform its competitors within a continuously growing market, but also in regard to the decrease of workforce related costs that both manufacturing and service companies must discharge.

Demand seasonality is a predictable phenomenon typically faced by the service sector that affects a company's usual personnel scheduling system since special needs must be met. Formulating such system becomes a challenging activity for the retail trade especially when unpredictable phenomena such as demand uncertainty and staff absenteeism are taken into account, for the mismatch between demand and supply ought to be reduced as much as possible [1 , 2 , 3]. As a result of the service industries' inherent variability, firms eventually face situations where the number of employees is below staff requirements (understaffing) or where there are more employees than the actual amount needed (overstaffing).

Therefore, in order to protect themselves from uncertainty and hence reduce the mismatch between employee supply and demand, enterprises apply several flexibility strategies such as a multiskilled staff [4 , 5 , 6 , 7]. By implementing this strategy in the retail industry, the operational manager of a retail store is able to transfer multiskilled employees from overstaffed departments to those understaffed. However, since training employees is costly, it is necessary to identify efficient multiskilling designs in order to obtain a maximum of benefits from this approach at a reasonable cost.

Assigning multiskilled staff to different activities can be modeled as an assignment problem in a bipartite graph where the supply nodes are employees, and the demand nodes are the departments of a store. These types of designs are known as chained multiskilling designs where different multiskilling structures can be arranged. Amongst the most evaluated structures by previous works in the literature we can find closed long chains (CLC) and closed short chains (CSC). A CLC is a bipartite graph where there is a multiskilled employee in each department so that its arcs form exactly one undirected cycle, while a CSC is an induced bipartite subgraph that forms an undirected cycle since there is a subset of multiskilled employees that only connects a subset of departments.

Particularly, the 2-chaining policy, where certain employees are trained in two departments, i.e., k =2, has been acknowledged by many studies as the most popular and endorsed chaining policy [4 , 6 , 8 , 9 , 10 , 11]. However, it would be interesting to analyze scenarios where a certain number of employees are able to work in k departments with k≥2. This type of policy is known as k-chaining and only a few studies have evaluated its benefits before. Figure 1 shows a comparison between a 2-chaining structure with one CLC and one CSC, and a k-chaining structure with k=3.

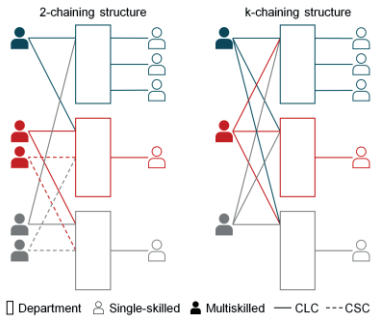

Fig. 1. Comparison between a 2-chaining structure with one CLC and one CSC, and a k-chaining structure with k=3.

Therefore, the present study evaluates if it is possible to plan a multiskilled staff, using the k-chaining approach and considering demand uncertainty, that minimizes the expected costs associated with training and under /overstaffing for a days-off scheduling problem. A deterministic mixed-integer Linear Programming (MILP) model is initially proposed as a foundation for the stochastic analysis. Subsequently, a Two Stage Stochastic Optimization (TSSO) MILP model is developed and thus applied to a case study of a Chilean retail store.

2 Literature review

Previous studies have analyzed the multiskilling as a useful strategy to address scheduling personnel problems with the aim of minimizing the gap between demand and supply. A series of these articles is presented in Table 1. The following symbology is introduced to contextualize the main aspects in consideration:

1. *Decision level of Human Resources studied (ND-RH):* The ND-RH column indicates which decision problems were covered in each study. At the planning level, the main decision problem would be to determine the staffing by type of task and contract (S). At the scheduling level, the decision problems are: (i) shift scheduling (SS), that is, assigning employees to daily shifts; (ii) day off scheduling (DOS), that is, assigning employees to days off between their working days over a given planning horizon; and (iii) Tour scheduling (TS), that is, the simultaneous assignment of days off and shifts. Finally, the assignment level (A) simply consists of assigning employees to particular types of tasks regardless of their corresponding shifts.
2. *Chaining (CH):* Indicates if any sort of chaining application is present in the model, if there is not (-), if there is chaining in maximum two types of tasks (2-chaining), if there is chaining in three or more tasks types (k-chaining with k>2).
3. *Multiskilling (MS):* Indicates whether the study uses a parameter (Par) representing an employee's fixed skills or a variable (Var) representing the decision as to whether or not an employee is trained in a given additional task type.
4. *Constraint of maximum number of skills in the model (MSP):* Indicates the maximum number of skills per employee that the model allows for the solution.
5. *Number of skills in the solution (NSS):* Indicates the resultant value of the number of skills per employee present in the solution.
6. *System type (ST):* (i) homogeneous (Hom), meaning that all task types, departments or resources in the system are identical, each one having the same supply level and installed capacity as well as possessing an identical demand and level of productivity, multiskilling and probability of absenteeism; (ii) heterogeneous (Het), meaning that not all the task types or departments are identical.
7. *Demand uncertainty (DU):* Indicates whether or not the problem considers variability in the staff demand.
8. *Supply uncertainty (SU):* Indicates whether or not the problem considers variability of supply or staff absenteeism.

9. *Method:* Indicates the solution method used, may be: (i) heuristics (H); (ii) simulation (S); (iii) optimization (OPT); (iv) Markov processes (MP); (v) analytic (AN); (vi) queuing theory (QT); (vii) algorithm (AL); (viii) genetic algorithm (GA); (ix) constraint-based selection procedure (CODEMI); (x) constraint scheduling (CS) and (xi) statistical analysis (SA).
10. *Application (AP):* The industry or sector where the proposed model was applied in the study, which may be (i) manufacturing (M); (ii) services (S); (iii) call centers (CC); (iv) health (H); (v) retail (R); (vi) Power plant (CE); (vii) Cyber Security Operations Center (CS); (viii) Construction (C).

According to Table 1, in the vast majority of the studies the multiskilling effect it is entered as a fixed data input, which restricts the possibilities of obtaining better solutions This issue could be solved by using a decision variable instead.

Subsequently, it can be noticed that it is frequently concluded that by training the personnel in a maximum of one additional skill, optimal results are obtained in terms of budget and level of service. However, it is not common to execute chaining methods in the solution procedures, which are considered of utmost importance to evaluate the impact that its application may possibly cause in this type of systems in relation to a more accurate approach to the optimal number of additional skills required per employee.

In addition, we identify that in the scarcely articles where chaining is contemplated, the 2-chaining method is usually applied (k = 2), only few studies implement multi-skilling as an unrestricted decision variable for the purpose of developing k-chaining setups. It is also evident that a large section of articles does not evaluate demand uncertainty.

In summary, this study aims to fill the gaps identified from the literature review by solving a days-off-scheduling problem that minimizes the under/overstaffing costs, using a multiskilled staff with a k-chaining approach, and taking into account the demand uncertainty.

3 Problem description

The problem under study consists in planning a multiskilled workforce, over a two-week horizon, that helps mitigate the negative impacts of the inherent uncertainties involved in the personnel scheduling process. Specifically, the problem we propose addresses the retail industry and seeks to minimize the costs associated with training and personnel shortage/surplus. In addition, this research aims to define robust multiskilling structures through k-chaining policies with $k \geq 2$, involving CLCs and/or CSCs, for a days-off scheduling human resources decision level. Since training employees is costly, the solution of this problem will define the most cost-effective multiskilling structure that not only minimizes the training cost but also guarantees robusticity against different levels of demand variability.

Briefly, the solution of this problem will determine: (i) how many employees should be single-skilled and how many should be multiskilled; (ii) the amount of additional skills each multiskilled employee should have; and (iii) under what levels of demand uncertainty a 2-chaining policy or a k-chaining policy with $k \geq 2$ is required. The solution will also assign rest days between working days to each employee over the two-week planning horizon.

In order to obtain those results, we formulate deterministic (see section 4.1) and stochastic (see section 4.2) models that consider the following assumptions: (i) Training costs are included in the total cost function and assumed to be the same for each department. (ii) The staff shortage/surplus cost per person-hour is assumed to be the same for each department and independent of the size of the staff shortage/surplus. (iii) The hours available for assignment in any department at the start of the planning horizon are exactly equal to the value in hours of that department's mean demand. (iv) There is no uncertainty of supply, that is, no staff absenteeism. (v) All employees have the same contract and therefore work the same number of weekly hours. (vi) Each employee should get at least one weekend off during the two-week planning period. (vii) At the start of the planning horizon, all employees are single-skilled and, thus, they can work only in a single department. (viii) Employees are homogeneous, i.e. all equally productive.

4 Methodology

The objective of the present section is to structure a workforce using the k-chaining approach for a days-off scheduling problem while considering uncertain demand. In Subsection 4.1, a deterministic optimization model is proposed for solving the addressed problem. Then, in Subsection 4.2, we present a two-stage stochastic optimization model for determining the robust multiskilling levels that minimize the expected under/overstaffing and training costs.

4.1 Deterministic optimization model

In this subsection we present a deterministic version of the mixed-integer linear programming model useful to solve the personnel days-off scheduling problem with k-chaining. Later, in Subsection 4.2, we will introduce the necessary modifications to incorporate demand uncertainty. First, let us define the model's sets, parameters and variables and their respective notation.

Model sets:

I : Store employees, indexed by i.

L : Store departments, indexed by l.

I_l : Store employees under contract in department l , $I_l \subseteq I, \forall\ l \in L$

S : Weeks, indexed by s. {1, 2}.

D : Days of the two-week period, indexed by d {1, 2, ..., 13,14}

D_S : The set of days during week s of the two-week period.

$D5_d$: Next five consecutive days in the two-week period after day d . For example, $D5_2$ = {3, 4, 5, 6, 7}, where day 2 corresponds to the first week's Tuesday and day 7 corresponds to the first week's Sunday.

D^+ : Maximum consecutive days, indexed by d {1, 2, ..., 8, 9}.

Model parameters:

c : Cost of training an employee to work in any department; [$-biweek/employee].

u : Staff shortage cost per hour (equivalent to the expected cost of lost sales); [$/Hour].

o : Staff surplus cost per hour (equivalent to the opportunity cost of idle employee-hours); [$/Hour].

r_{ld} : Number of hours required in department l on day d , $\forall l \in L$, $d \in D$.

t : Number of daily hours employees must work under store employment contract.

m_i : Department for which employee i was initially trained, $\forall\ i \in I$.

Model decision variables:

x_{il}: Equal to 1 if employee i is trained for department l, otherwise 0, $\forall i \in I$, $l \in L$.

y_{id}: Equal to 1 if employee i works on day d, otherwise 0, $\forall i \in I$, $d \in D$.

ω_{ild}: Number of working hours assigned to employee i on day d in department l, $\forall i \in I$, $l \in L$, $d \in D$.

z_i: Equal to 1 if employee i does not work on the first weekend (day 6, day 7) and 0 if employee i does not work on the second weekend (day 13, day 14) $\forall i \in I$.

v_i: Number of additional skills for employee i, $\forall i \in I$.

k_{ld}: Staff shortage in daily hours in department l on day d, $\forall l \in L, d \in D$.

δ_{ld}: Staff surplus in daily hours in department l on day d, $\forall l \in L, d \in D$.

The deterministic mixed-integer linear programming (MILP) model can now be formulated as follows:

$$Min \underbrace{\sum_{i \in I} \sum_{l \in L: l \neq m_i} c x_{il}}_{(a)} + \underbrace{\sum_{d \in D} \sum_{l \in L} (u k_{ld} + o \delta_{ld})}_{(b)} \tag{1}$$

s.t.

$$\sum_{i \in I} \omega_{ild} + \kappa_{ld} - \delta_{ld} = r_{ld} \qquad \forall l \in L, d \in D \tag{2}$$

$$\omega_{ild} \leq t x_{il} \qquad \forall i \in I, l \in L, d \in D \tag{3}$$

$$\sum_{l \in L} \omega_{ild} = t y_{id} \qquad \forall i \in I, d \in D \tag{4}$$

$$\sum_{d \in D_S} y_{id} = 5 \qquad \forall i \in I, s \in S \tag{5}$$

$$y_{id} + \sum_{\bar{d} \in D5_d} y_{i\bar{d}} \leq 5 \qquad \forall i \in I, d \in D^+ \tag{6}$$

$$y_{id} \leq 1 - z_i \qquad \forall i \in I, d \in \{6,7\} \tag{7}$$

$$y_{id} \leq z_i \qquad \forall i \in I, d \in \{13,14\} \tag{8}$$

$$x_{il} = 1 \qquad \forall i \in I, l \in L : l = m_i \tag{9}$$

$$v_i = \sum_{l \in L: l \neq m_i} x_{il} \qquad \forall i \in I \tag{10}$$

$$\sum_{i \in I_l} v_i = \sum_{i \in [I - I_l]} x_{il} \qquad I_l \subseteq I, \quad \forall l \in L \tag{11}$$

$$z_i \in \{0,1\} \qquad \forall i \in I \tag{12}$$

$$x_{il} \in \{0,1\} \qquad \forall i \in I, l \in L \tag{13}$$

$$y_{id} \in \{0,1\} \qquad \forall i \in I, d \in D \tag{14}$$

$$v_i \geq 0 \qquad \forall i \in I \qquad (15)$$

$$k_{ld} \geq 0 \qquad \forall l \in L, d \in D \qquad (16)$$

$$\delta_{ld} \geq 0 \qquad \forall l \in L, d \in D \qquad (17)$$

$$\omega_{ild} \geq 0 \qquad \forall i \in I, l \in L, d \in D \qquad (18)$$

In this formulation the objective function (1) minimizes the following costs: (a) training of employees in additional skills; and (b) staff shortage/surplus. Constraints (2), (16) and (17) yield the level of (non-negative) staff shortage/surplus associated with each department. Constraint (3) ensures the employees work the number of hours required by the employment contract only in departments they have been trained for. Constraint (4) guarantees the employees work the number of daily hours required by the employment contract only on the days they have been scheduled to work. Constraints from (5) to (8) implement days off scheduling constraints developed by Altner et al. [26]. Constraint (5) ensures each employee works exactly five days per week. Constraint (6) guarantees each employee works at most five consecutive days. Constraints (7) and (8) ensure each employee gets at least one weekend off. Constraints from (9) to (11) implement k-chaining constraints. Constraint (9) determines the department each employee was originally trained for. Constraint (10) indicates the number of additional departments an employee is trained for. Constraint (11) guarantees that for each department *l*, the number of employees belonging to it that have also been trained to work in other departments, is equal to the number of employees belonging to other departments that have been reciprocally trained to work in department *l*. Constraint (11) also ensures the formation of long or short closed chains. Either case requires that the indegree of each supply node belonging to the chain is equal to the outdegree of its corresponding demand node. Finally, constraints (12)-(18) define the domain of each problem variable.

4.2 Two stage stochastic optimization model

As mentioned before, in this subsection it is intended to describe the modifications applied to the original deterministic model in order to incorporate demand uncertainty in the stochastic model.

The approach that will be used to incorporate the uncertainty assumes that uncertainty is present in certain parameters of the problem, being denoted by ε. Along with this fact, it also assumes that the probability distribution of these uncertain parameters is perfectly known and deducted from historical data. The two-stage stochastic optimization (TSSO) approach begins by dividing into two sets the decision variables: first-stage and second-stage. The first-stage variables are represented by the vector *x*, and are decisions known as "here-and-now" because they are made before the actual perception of the uncertain parameters becomes available. The second- stage variables, *y(x)*, known as "wait and see" are taken after the realization of uncertainty and in consequence they can be denoted as $y(x, \varepsilon)$.

In addition, the TSSO problems are commonly solved by the sample average approximation (SAA) approach that creates one set of second-stage variables for every possible scenario. The quality of the SAA approach is high when it is generated a large enough, although finite, set of samples from the continuous distribution of the random parameters ε, represented by $\varepsilon \in \otimes$, where $\otimes$ is the set of scenarios generated. The first-stage variables x_{il}, v_i are related to decisions about train employees in a different department. These tactical decisions are made before the random realizations of the weekly demand are known. The second-stage variables, $\omega_{ild}(\varepsilon), k_{ld}(\varepsilon), \delta_{ld}(\varepsilon)$ are the operational adjustments once the uncertain demand in each department, $r_{ld}(\varepsilon)$ is observed. That is, after demands become known, staff shortages or surpluses may occur.

Taking this under appreciation, the two-stage stochastic MILP model can now be formulated as follows:

$$Min \quad \underbrace{\sum_{i\in I}\sum_{l\in L: l\neq m_i} cx_{il}}_{(first-stage)} + \underbrace{\frac{1}{|\otimes|}\left[\sum_{d\in D}\sum_{l\in L}\sum_{\varepsilon\in\otimes} (uk_{ld}(\varepsilon) + o\delta_{ld}(\varepsilon))\right]}_{(second-stage)} \tag{19}$$

s.t.

$$\sum_{i\in I}\omega_{ild}(\varepsilon) + \kappa_{ld}(\varepsilon) - \delta_{ld}(\varepsilon) = r_{ld}(\varepsilon) \qquad \forall l\in L, d\in D, \varepsilon\in\otimes \tag{20}$$

$$\omega_{ild}(\varepsilon) \le tx_{il} \qquad \forall i\in I, l\in L, \varepsilon\in\otimes \tag{21}$$

$$\sum_{l\in L}\omega_{ild}(\varepsilon) = ty_{id} \qquad \forall i\in I, d\in D, \varepsilon\in\otimes \tag{22}$$

$$\sum_{d\in D_S} y_{id} = 5 \qquad \forall i\in I, s\in S \tag{23}$$

$$y_{id} + \sum_{\bar{d}\in D5_d} y_{i\bar{d}} \le 5 \qquad \forall i\in I, d\in D^+ \tag{24}$$

$$y_{id} \le 1 - z_i \qquad \forall i\in I, d\in\{6,7\} \tag{25}$$

$$y_{id} \le z_i \qquad \forall i\in I, d\in\{13,14\} \tag{26}$$

$$x_{il} = 1 \qquad \forall i\in I, l\in L: l = m_i \tag{27}$$

$$v_i = \sum_{l\in L: l\neq m_i} x_{il} \qquad \forall i\in I \tag{28}$$

$$\sum_{i\in I_l} v_i = \sum_{i\in[I-I_l]} x_{il} \qquad \forall l\in L \tag{29}$$

$$z_i \in \{0,1\} \qquad \forall i\in I \tag{30}$$

$$x_{il} \in \{0,1\} \qquad \forall i\in I, l\in L \tag{31}$$

$$y_{id} \in \{0,1\} \qquad \forall i\in I, d\in D \tag{32}$$

$$v_i \ge 0 \qquad \forall i\in I \tag{33}$$

$$k_{ld}(\varepsilon) \ge 0 \qquad \forall l\in L, d\in D, \varepsilon\in\otimes \tag{34}$$

$$\delta_{ld}(\varepsilon) \geq 0 \qquad \forall l \in L, d \in D, \varepsilon \in \otimes \tag{35}$$

$$\omega_{ild}(\varepsilon) \geq 0 \qquad \forall i \in I, l \in L, d \in D, \varepsilon \in \otimes \tag{36}$$

In this formulation the objective function (19) minimizes the following costs: First-stage, training of employees in additional skills; and Second-stage, expected staff shortage/surplus. In summary, the constraints (2)-(4) and (16)-(18) were modified to explicitly incorporate uncertainty. Note that all these constraints involve only second-stage variables. Thus, the constraints (5)-(15) did not receive any modification because they are associated with first-stage variables. In addition, note that the interpretation of the constraints (20)-(36) and the constraints (2)-(18) is the same.

5 Computational experiments

The developed methodology was applied to a case study of a Chilean retail store. Regarding the deterministic model (1)-(18), it was written in AMPL and solved using the software CPLEX running through a computer with a random-access memory of 4 gigabytes. Regarding the TSSO model (19)-(36), it was also written in AMPL and solved using the software CPLEX running through NEOS-server, a free internet-based service for solving numerical optimization problems, subjected to a computational restricted time limit of 8 hours. The following subsections will elaborately describe the case study considered and the results obtained from the approach used.

5.1 Case study

We use real and simulated datasets to solve the proposed methodology. As to the real dataset, information concerning the size of the departments, initial skills of each employee and type of contract assigned to each employee, was retrieved from the Chilean retail store considered in this study. A total of 30 employees were analyzed within a 6 department store, that is, $|I| = 30$ and $|L| = 6$. A 9-hour full-time contract was assumed for the whole workforce; hence all employees should work exactly 5 days per week, resulting in 45 hours per week.

As for the costs parameters, the one related to staff shortages is equal to $u = US\$\ 60/h$ while staff surpluses represent a cost of $o = US\$\ 15/h$ [27]. The training cost per employee is assumed minimal, that is, $c = US\$\ 1\text{-}biweek/employee$. Since training employees is almost free of charge, the results obtained from this research could be evaluated as an upper bound on the potential beneficence of multiskilling [1 , 9 , 10].

In this study we considered the correspondent in-sample data, which alludes to the initial information used to attain the Multiskilled Personnel Days-off Scheduling Problem solution with uncertain demand. We used the TSSO approach, which is solved using a SAA method. To obtain this in sample-data we appeal to a classic Monte Carlo simulation to generate 60 scenarios at random which in the same way represent the possible future parameters of the daily demand $r_{ld}(\varepsilon) \quad \forall l \in L, d \in D, \varepsilon \in \otimes$, such that $|\otimes| = 60$.

This exact procedure is repeated as many times as possible to produce proper random demand values for each department under three coefficients of variation (CV) of the demand, which were 10%, 30% and 50%. Followed by these values, we assign a zero-truncated normal distribution to the stochastic demand in each department to avoid negative demand values which are not possible events.

For the purpose of studying the multiskilling levels defined using the k-chaining approach, the following metrics were evaluated.

First, the percentage of multiskilled employees: number of multiskilled employees required in relation to the total number of hired employees.

$$\%ME = \frac{\sum_{l \in L} \lambda_l}{|I|}.100 \tag{37}$$

Second, the percentage of multiskilled employees with h additional skills: number of multiskilled employees with h additional skills in relation to the total number of hired employees. Being m_{lh} the number of multiskilled employees belonging to department l with h additional skills,

$$\%ME_h = \frac{\sum_{l \in L} m_{lh}}{|I|}.100 \qquad \forall h \in \{1,2,3,4,5\} \tag{38}$$

Third, the percentage of total multiskilling: Number of additional skills that have been trained, relative to the theoretical maximum, in this case 150.

$$\%TM = \frac{\sum_{i \in I} \sum_{l \in L: l \neq m_i} x_{il}}{|I|(|L|-1)}.100 \tag{39}$$

5.2 Results and discussion

In order to analyze the results obtained from applying the methodology developed to a Chilean retail store, various aspects regarding both the deterministic and stochastic models will be presented. As expected, the computational time was way higher for the TSSO zero-truncated (TSSO-ZT) problem than for the deterministic one (DT). Apropos of the size of each model, the following table exhibits some important measures.

Table 2. Size of the deterministic and stochastic models

Model	Constraints	Binary variables	Continuous variables
TSSO-ZT	156 738	600	161 322
DT	3 102	600	2 730

Multiskilling decisions. Table 3 presents the results obtained once each of the metrics presented in the case study section was evaluated. Figure 2 shows the number of employees trained in one additional skill (k=2) and two additional skills (k=3) for each CV.

Table 3. Metrics used to measure the multiskilling requirements.

%CV	%ME	$\%ME_1$	$\%ME_2$	%TM
10	47	40	7	11
30	83	80	3	17
50	100	77	23	25

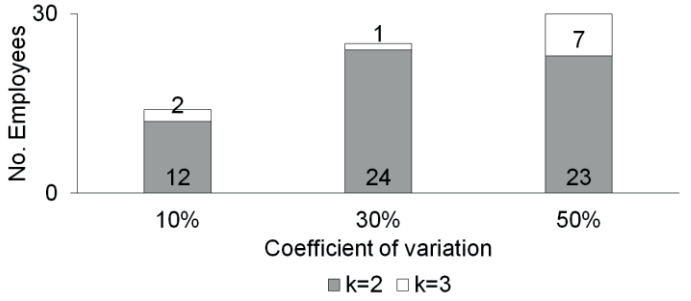

Fig. 2. Number of multiskilled employees trained in one additional skill (k=2) and two additional skills (k=3).

For a stochastic problem where 60 demand scenarios were generated, the ME, ME_1 and TM increase as the coefficient of variation rises. As to the ME_2, its greatest and lowest percentage are achieved at the CV = 50% and 30% respectively, behavior that could be explained by the quantity of demand scenarios analyzed.

It is also observed that when the demand variability is the highest (i.e., CV=50%) the ME reaches its theoretical maximum. Since the problem does not constraint the amount of additional skills an employee can acquire, it is expected that the resulting levels of multiskilling for the CV= 50% are those that not only most likely minimize the under/overstaffing cost, but also work as an upper bound on the potential beneficence of multiskilling considering the low training cost employed. The maximum amount of additional skills obtained was two, that is, there are some employees who are able to work in three different departments.

As to the highest level of demand variability, every single employee is multiskilled, just as assured before with the ME metric. In this scenario, 7 out of 30 employees were trained in two additional skills and the remaining 23 were trained in one additional skill.

Although the maximum number of employees trained in more than one additional skill is obtained at the CV= 50%, at both CV= 10% and 30% some employees are able to work in more than 2 departments. These results demonstrate that k-chaining policies with $k \geq 2$ are convenient, especially when the demand variability levels are high. It could also be concluded that flexibility structures with $k>3$ are not quite attractive since such amount of multiskilling could be impractical. However, a larger amount of demand scenarios should be evaluated in order to make a more objective statement.

Days-off-scheduling decisions. Figure 3 shows the number of employees assigned in each day of the second week of the planning horizon, indicating if the employee is single-skilled, trained in one additional skill (k=2) or trained in two additional skills (k=3), considering the demand variability with CV = 10%, 30% and 50%. It is observed that when the demand variability is low (CV = 10% and 30%) there are more employees assigned to work on the weekends (Saturday and Sunday), but as the demand variability increases (CV = 50%) the number of employees assigned to work on the weekends is less or equal to any other day of the week. Also, when the demand variability is the lowest (CV = 10%) there are more single-skilled employees, but these decrease in inverse proportion with the CV, and when the demand variability is the highest (CV = 50%) all employees are multiskilled.

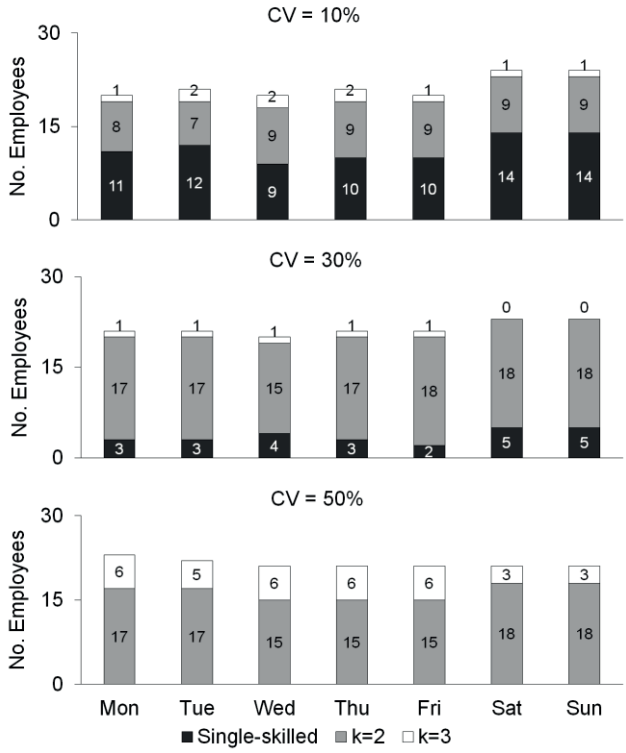

Fig. 3. Number of employees assigned in each day of the second week of the planning horizon.

6 Conclusions

Through the development of this study we were able to demonstrate how, under a series of realistic conditions of demand uncertainty, it is profitable and advisable to apply multiskilling setups using k-chaining with k≥2. It was observed that the number of multiskilled employees needed grows as the demand variability increases. This is explained

because it is crucial to count on a strong organization and programing of multiskilled employees that will keep us prepared to cover the majority of attainable scenarios in the practice, and this is also why the resultant percentage of multiskilled employees with a 50% coefficient of variation in the demand is consequently of the 100%. Among some of the assumptions of the model, we suppose that the training cost is minimal and the productivity of an employee will be identical from one another and independent from the quantity of additional skills that he/she has been trained in. Nevertheless, the study shows that total multiskilling is not required to obtain maximum profits. Finally, the study also proves that k-chaining policies with $k \geq 2$ are convenient, especially when the demand variability levels are high.

Abstract. In this article, heuristics methods are proposed for the sequence-dependent setup times m-machine blocking flow shop scheduling problem with hierarchical function of minimizing total completion time given that preventive total maintenance costs must be equal or lower than a certain value. A greedy randomized adaptive search procedure (GRASP), a discrete artificial bee colony algorithm (DABC) and a variable blocking insertion heuristic (VBIH) are adapted to minimize the hierarchical objective function. A procedure to assign PM operations is proposed to improve final solutions given by the adapted algorithms. All the methods were tested over a set of 11,520 problems. Computational results show that VBIH presented the best trade-off between effectiveness and efficiency. Additionally, statistical results show that the proposed procedure significantly improved solutions given by evaluated algorithms.

Keywords: scheduling, blocking flow shop, preventive maintenance, sequence dependent setup times, total completion time

1 Introduction

In most of m-machine flow shop scheduling problem literature, machines are considered always available to process jobs. Over the last years, some researches has been incorporated practical machines unavailability aspects to the scheduling problem (See e.g. [1] for a review of literature). Among machine availability constraints, this article focuses on preventive maintenance (PM) operations. Although job and PM activities scheduling are separately treated in literature, they are closely related to each other. While postponing processing of jobs to carry out a PM activity may delay the due date of jobs, the continuously processing of jobs may increase the probability of occurrence of a machine breakdown [2]. In flow shop scheduling problems, PM activity can be considered as fixed and known to a determined period ([3]) or flexible, i.e., it can be carried out inside an interval period T ([4], [5]). PM operations can also be modeled according to frequencies or PM statistical models ([2], [6]). In other cases, as in [7], [8], the

flow shop scheduling problem is integrated PM based on the condition of the machine.

Another common assumption in most of scheduling problems is the consideration of infinite capacity buffers. For reasons of technological restrictions, some production environments deals with the lack of intermediate storage between machines, a constraint known as blocking. This condition implies that, once the current job is finished, it must be kept on the current machine until the previous job is finished on the next machine. Thus, a blocking time is caused by the current job on the current machine until the previous job is finished and released from the following machine to the next. Examples of blocking flow shop can be seen in iron and steel industry, in the treatment of industrial waste and manufacture of metallic parts [9], in some stages of productive process as in concrete block production [10] or in robotic cells, where the job is kept on machine until it is picked it up by the robot to move it to the next stage [11]. A survey and a review of literature of the m-machine blocking flow shop scheduling problems can be seen in [12] and [13], respectively.

This article aims to propose heuristic methods for the sequence-dependent setup m-machine blocking flow shop with preventive maintenance based on machine deterioration condition to minimize total completion time (TCT) subject to total PM costs bound (PM_{cost}_B). The concept of PM based on machine deterioration condition was first presented by Bock et al. [14] in single machine scheduling problem. Recently, Yu and Seif [7] and [8] extended the aforementioned problem to blocking flow shop and no-wait flow shop, respectively, both adopting makespan minimization as objective-function. The measure considered in this article is known in literature as hierarchical function [15], where the target of the problem is to minimize TCT given that the total PM costs PM_{cost} must be lower or equal to a certain value. For the best of authors knowledge, this is the first article to study this problem.

The remaining sections are structured as follows: In Section 2, the problem is formally described and procedures to assign PM activities to job sequence are presented. Solution methods composed by a constructive heuristic and metaheuristics are proposed in Section 3. Section 4 shows the details of the computational experiments and the performance evaluation of the algorithms. Final considerations can be seen in Section 5.

2 Problem definition

The problem is stated as follows: a sequence of n jobs must be processed through m machines. All jobs follow the same pattern flow and the sequence established in the first machine is the same to the remaining machines. Operation of Job i has an associated processing time on machine j denoted as $p_{i,j}$. Setup time to prepare machine j to process job k after processing job i ($s_{j,i,k}$) is sequence-dependent and it is separated from the processing times. Preemption is not allowed. Release dates of all jobs are equal to zero. There are no buffers between subsequent machines, consequently, a finished job i on machine j must wait job

i-1 to be processed on machine j+1. Because of the absence of intermediate storage, job i is kept on machine j until job i-1 is finished and released from machine j+1. All machines are subject to preventive maintenance (PM) activities. PM actions are defined by level t ($t = 1, \ldots, l$), where each of them has an amount $ML_{t,j}^{max}$ available to process jobs. Figure 1 illustrates the considered problem. Deterioration rates, denoted as $\delta_{i,j,t}$ and $v_{j,i,k}^{t}$, is associated with processing and setup times of each job i, respectively.

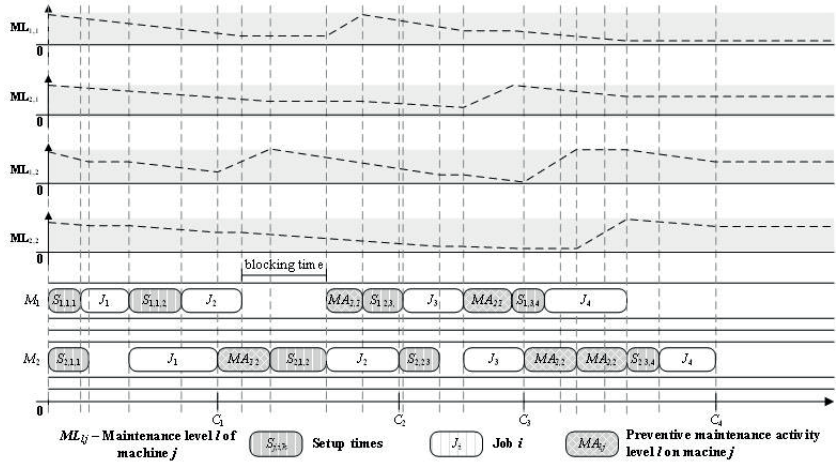

Fig. 1. 2-machine sequence-dependent blocking flow shop with 2 preventive maintenance levels

Deterioration level t of machine j before and after processing job k are denoted as $ML_{t,j,k}$ and $\overline{ML}_{t,j,k}$, respectively. Before the first job processed, each PM level t $ML_{t,j,1}$ is at its maximum, i.e., $ML_{t,j,1} = ML_{t,j}^{max}$. When job k is processed, being job i its adjacent, the value of $ML_{t,j,k}$ is updated with $\overline{ML}_{t,j,i}$ and the value of $\overline{ML}_{t,j,k}$ is equal to $ML_{t,j,k}$ - $p_{k,j} \times \delta_{k,j,t} + s_{j,i,k} \times v_{j,i,k}^{t}$. Each job is evaluated until $\overline{ML}_{t,j,k}$ reaches a value below zero, which indicates that $ML_{t,j,k}$ is insufficient to cover the next job k. In theory, a value of $\overline{ML}_{t,j,k} < 0$ means the occurrence of a machine breakdown. To prevent the failure, a PM level activity t on machine j with duration $MA_{t,j}$ is carried out before the processing of job that causes the negative value of PM level t of machine j to restore its condition to the maximum value, i.e., $ML_{t,j,k} = ML_{t,j}^{max}$). A PM activity t of machine j between adjacent jobs i and k is denoted as $MA_{j,i,k}^{t}$ and receives value $MA_{t,j}$ if $ML_{t,j} < 0$, and 0 otherwise. To ensure the feasibility of the problem, the quantity $(p_{i,j}) \times (\delta_{i,j,t}) + (s_{j,i,k}) \times (v_{j,i,k}^{t})$ must be less or equal than $ML_{t,j}^{max}$. Each PM activity of level t on machine j has an associated cost which is composed by the sum of all spare parts costs ($SP_{t,j}$) and workforce costs (WF_t) per unit of time (u.t.), i.e., $WF_t \times MA_{t,j}$. The total PM costs (PM_{cost}) corresponds to the sum of all PM activities carried out during the scheduling planning. The objective-function of the problem aims to minimize the sum of departure times of all jobs on the last machine, i.e. the sum of departure times ($\sum_{i=1}^{n} D_{i,m}$), given that the value of PM_cost must be equal or lower than a

certain value PM_{cost}_B. The computation of departure time of job assigned to position i on machine j ($D_{i,j}$) can be described as follows:

$$D_{1,j}=max\{D_{1,j-1};s_{j,1,1}\}+p_{1,j} \quad j=1,...,m \tag{1}$$

$$D_{i,1}=D_{i-1,2}+\sum_{t=1}^{l} MA_{j,i-1,i}^{t}+s_{j,i-1,i}+p_{i,1} \quad i=2,...,n \tag{2}$$

$$D_{i,j}=max\left\{D_{i,j-1};D_{i-1,j+1}+\sum_{t=1}^{l} MA_{j,i-1,i}^{t}+s_{j,i-1,i}\right\}+p_{i,j} \quad j=2,...,m-1 \quad i=2,...,n \tag{3}$$

$$D_{i,m}=max\left\{D_{i,m-1};D_{i-1,m}+\sum_{t=1}^{l} MA_{m,i-1,i}^{t}+s_{m,i-1,i}\right\}+p_{i,m} \quad i=2,...,n \tag{4}$$

Where $D_{1,0} = 0$. Since PM_{cost}_B is used as a constraint, the evaluation function accepts the candidate sequence π only if $PM_{cost}(\pi)$ is lower or equal the PM_{cost}_B and if $TCT(\pi)$ is lower than TCT of the current sequence ($TCT(\pi')$), as described on Alg. 1.

Algorithm 1: Evaluation procedure for solution quality

```
if PM_cost(π) ≤ PM_cost_B then
    if TCT(π) < TCT(π') then
        π' ← π;
    end
end
```

Since the m-machine blocking flow shop with TCT minimization scheduling problem is known as NP-Hard ([16]), the development of heuristic methods are feasible alternatives to solve the problem. In the next section, heuristic procedures to assign PM activities are proposed.

2.1 Procedure to assign preventive maintenance activities to job sequence

One of the aspects related with the jointly PM activities and jobs scheduling is how to integrate both activities. In this section two heuristics procedures are presented to incorporate PM activities to scheduling planning given a job sequence. The first procedure, proposed by [2], is applied to determine the total number of PM activities N_{PM} to maintain the m machines to process the n jobs and it is described as follows: When each job i is processed on machine j, the deterioration PM level t after processing job assigned to position i ($\overline{ML}_{t,j,[i]}$) is computed according to ($ML_{t,j,[i]}$ - $\upsilon_{j,q,}^{t}$ $\times$s$_{j,q,k}$ - $\delta_{k,j,t} \times p_{k,j}$). If $\overline{ML}_{t,j,[i]} < 0$, a PM activity with duration $MA_{t,j}$ is carried out before job assigned to position i, and $ML_{t,j,[i]}$ returns to $ML_{t,j}^{max}$ level. Otherwise, $ML_{t,j,[i+1]}$ receives $\overline{ML}_{t,j,[i]}$ and the next job is evaluated. The procedure is repeated until for all n jobs, considering each PM level of each machine.

The second procedure tries to improve the current sequence given by Ruiz's criterion. The local search, denominated $LS_{PM,RE}$ tries to reassign a PM activity to a prior position with the aim to minimize TCT without modify PM_{cost}. The

procedure starts the search setting the current sequence as candidate solution. Thus, $LS_{PM,RE}$ evaluates the possibility to move a given PM activity to a prior position regarding to its original position evaluating the minimization of TCT. Thus, $ML_{t,j,[k]}$ and $\overline{ML}_{t,j,[k]}$ are recalculated for all PM activities of level t of machine j, starting from the last $MA_{t,j}$. If $\overline{ML}_{t,j,[k]}$ generates a negative value when placed before job assigned to position k, originally placed prior before job that occupies position p, where k ¡ p, all positions between jobs k and p are evaluated and the sequence that generates the minimum TCT is hold. Next, the search continues with the last but one $MA_{t,j}$, which is evaluated from job k-1 until a prior job i, where k ¡ i that causes a negative value of $\overline{ML}_{t,j,[i]}$. In case of sequences with equal TCT, the sequence which $MA_{t,j}$ is placed to the most prior position is chosen. If a negative $\overline{ML}_{t,j,[k]}$ is caused by only one job, the procedure stops and the best sequence of the evaluation until then is kept as candidate solution. On the contrary, the procedure continues until the first PM activity of level t on machine j is evaluated. It is considered that the first PM activity is evaluated, if possible, from its original position until position between the first and second jobs. The best sequence found is retained as candidate solution. Thus, the next PM activity level t on machine j is evaluated. If TCT of best sequence found in the evaluation is lower than TCT of candidate solution, the new sequence becomes the candidate solution. The process is repeated until all l on all m machines are evaluated. If TCT of the best candidate sequence found is lower than TCT of the current sequence, the new one becomes the current sequence. $LS_{PM,RE}$ is repeated until no improvement is found. The criterion to evaluate the quality of solution of the sequences is described as follows: the procedure by Ruiz is used to generate the PM assignment of all sequences generated by all the methods. Then, $LS_{PM,RE}$ is applied only to final solution given by the proposed metaheuristics with the aim to minimize TCT.

3 Solution methods

Since the hierarchical function $TCT|PM_{cost}$ aims to minimize TCT given PM_{cost} bound, it is required to provide a total PM cost value bound (PM_{cost}_B). Here, the constructive method tPF-NEH(x), proposed by [17], is applied to generate initial sequence for all metaheuristics as well as to generate the PM_{cost}_B. For reasons of space, the description of tPF-NEH(x) will be omitted here. With some minor modifications, tPF-NEH(x) was adapted to the problem to minimize PM_{cost}. In order to minimize TCT, it is proposed the adaptation of recent metaheuristics designed for m-machine blocking flow shop with TCT minimization: GRASP-HPF2 by [18], VBIH by [17] and DABC_RCT by [19].

3.1 Greedy Randomized Adaptive Search Procedure

Ribas and Companys [18] proposed four versions of GRASP to minimize total completion time (TCT). Through experimental results, the author suggested the use of GRASP-HPF2 or GRASP-NHPF2. In this article, GRASP-HPF2 (Alg.

2) was adopted as an alternative to minimize $TCT|PM_{cost}_B$. Basically, the proposed GRASP is composed by a construction phase and a local search phase, which is run until a specified stopping criterion is reached.

In the first iteration of the algorithm, solution given by tPF-NEH(x) is used as current candidate π'. From the second iteration on, the constructive phase uses HPF2 (see [18] for more details) to generate the current candidate solution π', using only TCT as objective-function. As in [18], the value of μ is randomly selected from a uniform distribution between $\mu(U[\mu_{min}; \mu_{max}])$ according to the size of the instance problem (see section 4 for more details). Additionally, the value of λ is set as 0. After construction phase, local search phase is applied to the candidate sequence. The local search consists of a Variable Neighborhood Search (VNS), composed by two neighborhood structures: swap (LS1) and insertion (LS2). In this phase, VNS aims to minimize TCT given that PM_{cost} is lower or equal to the best sequence found during its application. In LS1, each job of the sequence is randomly selected and swapped with all jobs that follows it in the sequence. If the best neighbor found (π) during VNS is better than the current solution π'', it becomes the new solution and the process continues until all jobs are evaluated. In LS2, each job of the sequence is removed from its original position and inserted into all other possible positions of the sequence.

Algorithm 2: Pseudocode of GRASP-HPF2

```
Input: π', π'' ← tPF-NEH(x)(π); λ; μ_min; μ_max; PM_cost_B;
repeat
    μ = μ_min + (μ_max − μ_min) × random(0,1);
    if iteration ≠ 1 then
        π' ← HPF2(λ, μ);
    end
    π' ← localSearch(π');
    if PM_cost(π') ≤ PM_cost_B then
        if TCT(π') ≤ TCT(π'') then
            π'' ← π';
        end
    end
until stopping_criterion is met;
Apply LS_PM,RE to π'';
Output: π'', TCT(π''), π''(LS_PM,RE),TCT(π''(LS_PM,RE)).
```

If the best neighbor π' is better than the current sequence π'', it becomes the new current solution π'' and the process continues until all jobs are evaluated. As in LS1, jobs are selected at random. The first neighborhood structure is randomly selected with a probability of 50%. After exploring a neighborhood through LS1 or LS2, the optimum local π' is compared with current solution π'''. If there is an improvement in TCT with PM_{cost} equal or lower than $PM_{cost}(pi''')$, pi''' is updated and the search continues in the other neighborhood. This process is repeated until pi'' is no longer improved. Finally, if the TCT of the local

optimum π' is better than the best solution found so far π'' with PM_{cost} lower or equal PM_{cost}_B, then π'' receives π'.

3.2 Discrete Artificial Bee Colony

In this article, the most effective version of DABC proposed by [19], named DABC_RCT, is adapted as solution method for the problem and its outline can be seen in Alg. 3.

Algorithm 3: Pseudocode of DABC_RCT

```
Input: N_f, N_TNO, tPF-NEH(x)(π);
Generate the initial population with N_f individuals through STR-1;
while stopping criterion is not met do
    π_best ← best solution of the population;
    π_worst ← worst solution of the population;
    Employed bees phase: for π_best and another randomly selected π
     of the population do
        for k ← 1 to t do
            Apply TNO procedure;
        end
    end
    Onlooker bees: Apply path relinking procedure to a randomly
     selected solution π of the population;
    Scout bees: Generate a new food source through HPF2;
    if PM_cost(π_new) ≤ PM_cost_B then
        if TCT(π_new) ¡ TCT(π_worst) then
            π_worst ← π_new;
        end
    end
end
Apply LS_PM,RE to π_best;
Output: π_best, TCT(π_best), π_best(LS_PM,RE), TCT(π_best(LS_PM,RE)).
```

The algorithm starts with the generation of a set of N_f initial solutions. This set of solutions represents the initial food sources that will be explored by employed bees. Each food source is represented by a permutation of jobs. The first individual is generated by tPF-NEH(x). The remaining individuals are generated by HPF2 according to the same range values of μ tested in GRASP-HPF2, using only TCT as evaluation criterion.

After the initialization, the best and worst individuals are chosen as follows: the solution generated by the best constructive heuristic is set as $PM_{cost\,B}$ and $TCT(\pi')$. π_{best} is set as the individual that obtains $PM_{cost} \leq PM_{cost}_B$ and the minimum TCT of the population. The solution that obtains the worst PM_{cost} and TCT is chosen as π_{worst}. Next, the employed bees are sent to food source to evaluate their surroundings. In this phase, two employed bees are sent: the best one and another randomly selected from food source. In this phase, the Three

Neighborhood Operators (TNO) technique is used to enhance the exploration. TNO starts from randomly selecting two positions i and k, where $i < k$. In the following, three operators (See [19] for more details) are applied to the selected sequence and the best one among the three sequences generated is chosen, i.e., the sequence that generates both minimum PM_{cost} and TCT. This process is repeated N_{TNO} times. Next, the local search procedure used in GRASP-HPF2 is applied to the best obtained solution. If the new improved solution generates equal or lower PM_{cost} and lower TCT than the original sequence, then, the former replaces the latter. In the onlooker bee phase, a food source is established through information shared by the employed bees. In this phase, path relinking technique is applied. In this search process, the best sequence evaluated π', used as reference solution, and another picked up from the food source, used as the origin path π, are chosen. The path is built by interchanging moves with the aim to convert π into π'. Initially, both solutions are compared and jobs that are assigned to different positions in both sequences are detected. Next, the first job from π' assigned to a different position from π is interchanged with the job that are placed on that position. If the new solution generates lower or equal PM_{cost} and TCT lower than the original, it is kept. The process continues until π becomes equal to π'. If there are k jobs in different positions in π', k-1 movements are carried out, since the last one equals the reference sequence π. Thus, path relinking is carried out only if more than two jobs can be swapped. In the scout bee phase, a new food source is generated by HPF2 with the ranged values of μ. The new candidate solution (π_{new}) replaces the worst solution (π_{worst}) from the population only if the former is better than the latter, i.e., if $PM_{cost}(\pi_{new})$ $\leq PM_{cost}(\pi_{worst})$ and if $TCT(\pi_{new})$ ¡ $TCT(\pi_{worst})$. After scout bee phase, the procedure is repeated until a stopping criterion is met. As it will be seen in Section 4, besides the range values of μ, DAB_RCT has two parameters to be adjusted: The size of population (N_f) and number of iterations of TNO (N_{TNO}).

3.3 Variable Block Insertion Heuristic

Variable Block Insertion Heuristic (VBIH) was proposed by [17] to solve the m-machine blocking flow shop with TCT minimization. In VBIH, a block of jobs with initial size $bS = 1$ ($bS_{min} \leq bS \leq bS_{max}$) is removed from the current sequence π and it makes a mS_{max} number of block moves into the partial sequence, which is denoted as bIM(π,bS,mS_{max}). The best sequence amongst the mS_{max} generated goes under a Variable Local Search (VLS), which is composed by insertion and swap neighborhood structures with both guided by a reference sequence π^R. If the new sequence π'' generated by VLS is better than π, it replaces the current sequence. The size of bS continues the same as long as the sequence is improved. Otherwise, $bS \leftarrow bS + 1$ and a acceptance criterion based on simulated annealing is used to accept the inferior solution in order to escape from local minimum. This procedure is repeated until $bS \leftarrow bS_{max}$. Alg. 4 shows the outline of VBIH.

After $bS \leftarrow bS_{min} \leftarrow 1$, bIM() procedure is applied to sequence π. bIM() is a triplet-field that receives π, the size of block bS and the number of moves

mS_{max}. A block of jobs denoted as π_B with size bS are randomly selected and removed from the current sequence π. Then, each element from π_B is inserted into mS_{max} random positions of the partial solution π_p. The sequence π' that generates the minimum TCT and PM_{cost} is selected as the best sequence. The process is repeated until all jobs are from π_B are reinserted in π.

In the next phase of the algorithm, a Variable Local Search (VLS) is applied to solution given by bIM() π'. Referenced Insertion Search (RIS) and Referenced Swap Search (RSS) are employed as neighborhood structures LS1 and LS2, respectively. RIS tries to improve the solution, minimizing TCT with PM_{cost} lower or equals to $PM_{cost}(\pi')$, using a referenced sequence π^R which guides the procedure to choose the next job to be inserted. RSS tries to improve π' swapping job of position k to all other jobs of the sequence. A detailed description of VLS can be seen in [17].

Algorithm 4: Pseudocode of VBIH

```
Input: π‴, π^R ← tPF-NEH(x)(π); PM_cost_B; T;
while sopping_criterion is met do
    bS ← bS_min ← 1;
    while bS ≤ bS_max do
        π' ← bIM(π, bS, mS_max);
        π'' ← VLS(π^R, π');
        if PM_cost(π'') ≤ PM_cost_B then
            if TCT(π'') < TCT(π‴) then
                π, π‴, π^R ← π'';
            end
        else
            bS ← bS + 1;
            if PM_cost(π'') ≤ PM_cost_B then
                if r ¡ exp [(−TCT(π)−TCT(π''))/T] then
                    π ← π'';
                end
            end
        end
    end
end
Apply LS_PM,RE to π‴;
Output: π‴, TCT(π‴), π‴(LS_PM,RE),TCT(π‴(LS_PM,RE)).
```

After the local search phase, if TCT of new solution π'' is better than the current sequence π''', with $PM_{cost}(\pi'')$ is equal or lower than PM_{cost}_B, it becomes π'''. In the case of a worse TCT, but PM_{cost} lower or equals to PM_{cost}_B, the new sequence is accepted as incumbent sequence for the next iteration according to an acceptance criterion based on simulated annealing, described as $T = \tau\ P \times \frac{\sum_{i=1}^{n}\sum j=1^{m} p_{i,j}}{10\times n\times m}$, where τP is a parameter to be adjusted.

As shown in Alg. 4, a complete iteration of VBIH comprises the increment of $bS = 1$ until $bS = bS_{max}$. For the considered problem, it is noted that the mentioned process is highly costly in terms of computational time. In order to reduce computational efforts to adequate the method to the complexity of problem, an iteration is considered completed after the evaluation of π'' as current or incumbent solution, without considering the increase of bS.

4 Experimental results

The constructive and improvement heuristics were coded in Delphi 7. All experiments were performed in a PC Intel®Core(TM) i5-2500K CPU 3.30 GHz with 4 GB RAM under a 64 bits Windows 7 operating system. The PM interval duration of PM level t on machine j ($PM_{j,t}^{max}$) is established according to $PM_{j,t}^{max} = max(p_{i,j}) \times max(\delta_{i,j,t}) + max(s_{j,i,k}) \times max(\upsilon_{j,i,k}^{t})$.

Two instance problem datasets were generated to evaluate the performance of the methods. The first dataset, called adjustment parameter set are composed by $n = \{30,60,90,120,150\}$. The second, denominated medium and large size instance problems, is set as $n = \{10, 20, \ldots, 180\}$. In both sets, $m = \{5,10,15,20\}$, $l = \{1,2,3,5\}$ and setup duration = {10%, 50%, 100%, 125%} of the processing times. The specifications of the parameters generation can be seen in Table 1. For each combination between n, m, l and setup time rates, ten problems were generated. In total, 1,600 and 11,5200 problems were generated for parameter adjustment and large size instance problem data sets, respectively.

Table 1. Specification of parameters

Parameters	Specifications
Processing Times	[0, 99]; Random; Uniform Distribution, $i = 1, ..., n$; $j = 1, ..., m$
Setup times ($s_{i,j,k}$)	{10%; 50%; 75%; 125%} of the processing times i, $k = 1, ..., n$; $j = 1, ..., m$
Deterioration job rates	[0.1, 2] (One decimal place); Random; Uniform Distribution; $i = 1, ..., n$; $j = 1, ..., m$; $t = 1, ..., l$
Deterioration setup rates	[0.1, 2] (One decimal place); Random; Uniform Distribution; $i, k = 1, ..., n$; $j = 1, ..., m$; $t = 1, ..., l$
Workforce costs	WF_t = [500, 2,000]; Random; Uniform distribution; $t = 1, ..., l$
Spare Part costs	$SP_{j,t}$ = [1,000, 20,000]; Random; Uniform Distribution; $t = 1, ..., l$; $j = 1,..., m$

The effectiveness and efficiency of the algorithms were evaluated according to relative percentage deviation (RPD) and computational time. The relative percentage deviation (RPD) evaluates how much a given solution is far from the best solution found and is given by $RPD_{b,h,g} = 100 \times \frac{TCT_{g,b,h} - TCT_{best,b,h}}{TCT_{best,b,h}}$, where $RPD_{b,h,g}$ is the RPD of solution given by algorithm g for problem b of instance h, $TCT_{g,b,h}$ is the solution obtained by algorithm g for problem b of instance h and $TCT_{best,b,h}$ is the best solution found so far for problem b of instance h.

The stopping criterion of all metaheuristics was set according to three ranges of number of iterations (N_{it}): 40, 60 and 80. As each algorithm has different components, the CPU time of each N_{it} were recorded to evaluate the trade-off between quality of solution and computational time used. The efficiency of the methods were measured through average relative percentage computational time of algorithm g ($ARPT_g$), recently applied by [16], which is computed as $ARPT_g = \frac{\sum_{i=1}^{I} RPT_{i,h}}{I}$, where $RPT_{i,h} = \frac{T_{i,g} - ACT_i}{ACT_i}$ and $ACT_i = \frac{\sum_{g=1}^{G} T_{i,g}}{G}$, where

$RPT_{i,g}$ is the relative percentage computational time obtained by algorithm g for instance problem i, $T_{i,g}$ is the computational time of method g when applied to instance i, G is the number of algorithms considered, I is the number of instances of the database and ACT_i is the average computational times for instance i among all algorithms considered.

4.1 Computational performance evaluation

The IRACE software package [20] was applied to determine the parameters adjustment of all metaheuristics. For each algorithm, stop criterion was set as 80 iterations and IRACE was set with total number of experiments equals to 3,000. Parameter ranges $\mu(U[\mu_{min}; \mu_{max}])$ for GRASP-HPF2 and DABC_RCT were set as $\mu(U[0.1; 0.5])$ for $n \leq 30$, $\mu(U[0.2; 0.8])$ for $30 < n \leq 60$, $\mu(U[0.1; 0.5])$ for $60 < n \leq 90$, $\mu(U[0.2; 0.7])$ for $90 < n \leq 120$ and $\mu(U[0; 0.8])$ for $n > 120$. DABC_RCT was set with $N_f = 13$ and $N_{TNO} = 49$ and VBIH was set with $bS = 0.25$, $mS_{max} = 0.4$ and $\tau P = 0.9$. The performance of metaheuristics can be seen in Table 2. In order to measure the effectiveness of the proposed procedure, the solutions generated by GRASP-HPF2, DABC_RCT and VBIH through Ruiz PM assignment criterion is labeled as GRASP(N_{it})_S, DABC(N_{it})_S and VBIH(N_{it})_S. The application of $LS_{PM,RE}$ to the final solutions by GRASP(N_{it})_S, DABC(N_{it})_S and VBIH(N_{it})_S are labeled as GRASP(N_{it})_LS, DABC(N_{it})_LS and VBIH(N_{it})_LS. The CPU times of DABC_LS, GRASP_LS and VBIH_LS were obtained by the sum between the CPU time by DABC_RCT_S, GRASP_S and VBIH_S and the CPU time of $LS_{PM,RE}$ applied to each algorithm, respectively.

Regarding the quality of solution, in general, all versions DABC_RCT obtained the lowest mean RPD in comparison with all versions of GRASP-HPF2 and VBIH with the respective N_{it}. All versions of VBIH are competitive against DABC_RCT in quality of solution. On the other hand, GRASP(HPF2) presented the worst performance among the evaluated metaheuristics. Athough DABC_RCT presented the best performance in quality of solution, it is the algorithm that obtained the largest values of RPT, and consequently, CPU times.

Regarding N_{it}, all versions of VBIH are more efficient in comparison with GRASP-HPF2 and DABC_RCT. Figure 2 shows the means plot of the trade-off between ARPD $\times$ ARPT. The results indicated that VBIH(40)_S, VBIH(40)_LS, VBIH(60)_S, VBIH(60)_LS, DABC(80)_S and DABC(80)_LS obtained the best results. Additionally, the use of $LS_{PM,RE}$ improved the solutions given by DABC_S, GRASP(HPF2)_S and VBIH_S with a little increase in the mean ARPT. From the aforementioned algorithms, VBIH, in special VBIH(60)_LS seems to obtain the best trade-off between effectiveness and efficiency.

A non-parametric Kruskall-Wallis test was applied to statistically verify the performance of VBIH algorithms, DABC(80)_S and DABC(80)_LS, in order to evaluate the acceptance of the null hypothesis "H0 - the distribution of relative percentage deviation is the same across the evaluated algorithms". At a significance level of 5%, the Kruskall-Wallis test indicated the decision to reject the null hypothesis. The Dunn-Borrefoni *post hoc* analysis was conducted to evaluate a pairwise comparison between each evaluated to identify pair of algorithms

Table 2. Performance of the metaheuristics (best results highlighted in bold)

with different distributions of RPD. The results of the test can be seen in Table 3. The Dunn-Borrefoni *post hoc* analysis indicated that only DABC(80)_LS and VBIH(80)_LS presented an adjusted significance larger than 5%, which suggests that the null hypothesis cannot be rejected. Furthermore, Table 3 indicated significant statistical differences between VBIH(40)_LS, VBIH(60)_LS, VBIH(80)_LS and DABC(80)_LS and VBIH(40)_S, VBIH(60)_S, VBIH(80)_S and DABC(80)_S, respectively.

5 Final considerations

In this article, heuristic methods are proposed to solve the sequence-dependent setup times blocking flow shop with total completion time minimization given that total preventive maintenance costs (PM_{cost}) must be equal or lower than a certain value. Procedures to assign PM activities are proposed to minimize the objective-function. The constructive heuristic tPF-NEH(x) are adapted to provide PM_{cost} and initial sequence and the metaheuristics GRASP, DABC and VBIH are adapted to minimize $TCT|PM_{cost}B$. Experimental results show

that in the trade-off between quality of solution and computational time, VBIH, specially VBIH(60)_LS and VBIH(80)_LS, provided solutions with good quality in lower CPU time. Statistical analysis indicated that the developed procedure significantly improved the quality of solution given by the algorithms. Thus, the use of the procedure can be considered as part of the methodology to solve the problem. For future research, it is suggested the study and proposition of solution methods with the use of the procedure for the problem with other hierarchical function as makespan or total tardiness subject to PM_{cost}.

Abstract. This papers deals with the minimization of total weighted earliness and tardiness on identical parallel machines subject to common restrictive due windows. This problem is known to be NP-hard even for two machines. Since there is no reported solution procedure for instances with more than 40 jobs, we propose a family of fast heuristics, which are composed of four phases. First, jobs are sequenced according to priority rules. Second, jobs are assigned to machines using a greedy strategy. Third, a local search is performed to find a better distribution of jobs onto machines. Finally, two heuristics are applied for individually sequencing jobs in each machine, namely RN-RGH and RN-SEA. Results show that the algorithms based on RN-SEA consistently outperform the ones based on RN-RGH, however, with a cost of higher computing times.

Keywords: Scheduling, Identical parallel machines, Earliness and tardiness, Just-in-time, Heuristics

1 Introduction

Production scheduling problems have received an important attention from operational research practitioners for many years. However, traditional performance measures involve nondecreasing functions of jobs completion times, even though they neglect the costs that early jobs may incur [2]. The emergence of just-in-time (JIT) philosophy highlighted the importance of considering the cost structures associated with both earliness and tardiness (ET), which culminated in the rapid diffusion of nonregular performance measures. In many practical contexts, if a customer order goods from a supplier, a fixed delivery date is agreed upon. Commonly, the customer accepts a small deviation from this delivery date as there is an uncertainty degree on the supplier's side. This uncertainty may arise in different ways, such as machine breakdowns, resource availability, defects in raw materials, and other production issues. With that said, it may be suitable to negotiate a common due window. For a comprehensive survey of structural properties of related problems we refer to Rolim and Nagano [18].

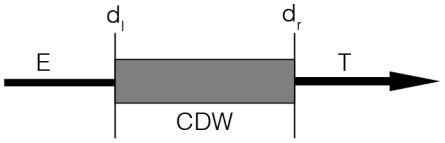
To the best of our knowledge, Kramer and Lee [13] were the first to provide an extension from the single machine environment to multiple parallel machines when the due window is not restricted (the left boundary of the window may be greater than the sum of processing times) and the ET weights are job independent and asymmetric. They show that this problem is NP-hard even for the unit weight case and provide a pseudopolynomial-time dynamic programming algorithm for the 2-machine case as well as a heuristic with absolute error bound. The heuristic is extended for an arbitrary number of machines. The error tends to decrease if the number of jobs is reasonably large.

Chen and Lee [6] provide a branch-and-bound algorithm for the case when the due window is restrictive and the weights are job-dependent. Their algorithm is based on the column generation approach in which the problem is first formulated as a set partitioning type formulation and then, in each branch-and-bound iteration, the linear relaxation of this formulation is solved by the standard column generation procedure. Results are reported for instances with up to 40 jobs.

Mosheiov and Oron [15] consider the due window assignment problem with unit processing times in identical parallel machines. They show that this problem is solvable in $O(1)$ time and provide several properties of an optimal solution. In a similar problem, but with job-dependent ET weights and an additional penalty for due-window size, Mosheiov and Sarig [17] give an efficient solution procedure that runs in $O(n^4)$. Janiak et al [11] extended this problem by adding a penalty for the left boundary of the due window and established conditions for optimal schedules. Other special cases that require less computational efforts are described. Gerstl and Mosheiov [9] shows that the general problem discussed by Janiak et al [11] can be solved by a lower order algorithm in $O(n^3)$ with some improvements.

The case of uniform parallel machines with identical processing times is reported by Mosheiov and Sarig [16] where they show that the two-machine environment may be solved in constant time. Gerstl and Mosheiov [8] assume that the due window can be either restrictive or non-restrictive. It was also assumed that the ET weights are job dependent and the jobs share an identical unit processing time. With that said, they propose $O(3^m n^3)$ and $O(2^m n^3)$ algorithms for restrictive and non-restrictive settings, respectively.

Janiak et al [12] address the problem of due window assignment and scheduling when jobs have independent earliness and tardiness costs, and penalties are also incurred for due window size and location. They establish a number of properties of optimal solutions and derive dynamic programming algorithms, which are pseudopolynomial if the number of machines is considered to be constant.



The main contribution of this paper is to propose alternative solution procedures to the problem defined by Chen and Lee [6] with an emphasis on computational efficiency. The only algorithm available in literature is reported to solve instances with up to 40 jobs in size. We show ten different heuristics to solve instances with up to 500 jobs and carry out extensive experiments to determine their performance. The remainder of this paper is divided as follows. Section 2 defines the problem and its structural properties. Then, in Section 3,

we describe phases 1 and 2 of the heuristics. Section 4 comprises the local search (phase 3). Section 5 is related to the sequencing aspects of each machine sub-problem (phase 4). We carry a discussion on the experimental results in Section 6 and, finally, Section 7 presents the concluding remarks as well as directions for further research.

2 Problem statement, definitions, and dominance properties

To a certain extent, the problem under study is similar to the one reported by Chen and Lee [6]. This problem consists of a set of n independent jobs, $N = \{1, 2, ..., n\}$, that need to be processed independently on any of the m ($m > 1$) identical parallel machines. The objective is to determine the sequence of all jobs so as to minimize the total weighted earliness and tardiness penalties. Using the well-known three field classification scheme introduced by Graham et al [10] and adapted by Rolim and Nagano [18] for scheduling problems with common due windows, the parallel machine scheduling problem (PMSP) can be expressed according to the notation $P|\langle \hat{d}_l, \hat{d}_r \rangle| \sum(\alpha_j E_j + \beta_j T_j)$, where $\langle \hat{d}_l, \hat{d}_r \rangle$ designates a common restrictive due window, that is, its left boundary must satisfy $d_l < \sum_{j=1}^{n} p_j$, E_j and T_j denote the earliness and tardiness of job $j \in N$, and α_j and β_j are job-dependent weights, respectively. A graphical representation of the due window is given in Fig. 1.

Fig. 1. Common due window representation

After being processed on the machine, and as a result of scheduling decisions, job j will be assigned a completion time denoted C_j. In other terms, the earliness and tardiness can be expressed as:

$$E_j = \max(d_l - C_j, 0) = (d_l - C_j)^+ \tag{1}$$

$$T_j = \max(C_j - d_r, 0) = (C_j - d_r)^+ \tag{2}$$

It is important to notice that, in contrast with tardiness penalties, earliness penalties are nonincreasing in C_j which makes the objective function a nonregular performance measure. For the common due window, let d_l and d_r be integers indicating the earliest and the latest due dates, respectively. Then, its size and location may be given as Eq. 3 and 4:

$$d_l = \lfloor h_l \times (\frac{\sum_{j=1}^{n} p_j}{m}) \rfloor \tag{3}$$

$$d_r = \lfloor h_r \times (\frac{\sum_{j=1}^{n} p_j}{m}) \rfloor \tag{4}$$

Here, h_l and h_r are given parameters for defining d_l and d_r, respectively. While the parameters h_l and h_r could be specified by any value, it is important to establish their ranges as $1 > h_r > h_l > 0$ so that the common due window becomes restricted by $0 < d_l < d_r < (\sum_{j=1}^{n} p_j/m)$. This configuration allows to avoid some trivial cases, for example, when $h_l = 0$ and $h_r = 1$ the common due window size would be, at least, close enough to $(\sum_{j=1}^{n} p_j/m)$, therefore, it could be possible to fit all jobs in the common due window. Moreover, if $h_l = h_r$, then the common due window could be reduced to a time instant, hence, no tolerance interval would exist, instead, it would be considered as a common due date. Other important assumptions are given as follows:

- All jobs are independent and ready at time zero.
- The machines can process only one job at a time.
- Jobs are processed without any interruptions, that is, machine breakdowns, planned or unexpected maintenance, and other effects that cause disruptions are not considered.
- The processing time of a given job is constant and cannot be compressed or expanded.
- No preemptions are permitted.

It is important to notice that the problem under study has some special characteristics that constitute optimal solutions. In a simplified way, these structural properties are given as follows:

- **Property 1**: There are no inserted idle times between jobs.
- **Property 2**: Jobs finishing before d_l are sequenced in nonincreasing order of the ratio p_j/α_j.
- **Property 3**: Jobs starting and finishing after d_r are sequenced in nondecreasing order of the ration p_j/β_j.
- **Property 4**: Jobs starting and finishing in the window can be sequenced in an arbitrary order.
- **Property 5**: In each machine, there exists an optimal schedule in which either the processing of the first job starts at time zero or one job is completed at d_l or d_r.

The proofs of these dominance rules can be found in Chen and Lee [6]. It is clear from properties 2, 3, and 4 that an optimal schedule follow the V-shaped property in each machine. Hereafter, the notations that will be used throughout the paper are established in Table 1.

It turns out that optimal schedules may have several different configurations. For this reason, we adopt the mapping procedure in Biskup and Feldmann [5] to

Table 1. Notations

Notation	Description
d_l	Left border of the common due window
d_r	Right border of the common due window
n	Number of jobs
m	Number of machines
j, k, l	Index of a job
i	Index of a machine
p_j	Processing time of job j
α_j	Earliness penalty of job j per time unit
β_j	Tardiness penalty of job j per time unit
E_j	Earliness of job j
T_j	Tardiness of job j
$s_{[l]}$	Leading idle time, i.e. starting time of the first job
C_j	Completion time of job j
S_j	Starting time of job j
J_E	Set of no-tardy jobs scheduled to finish before or in d_l, $J_E = \{j \vert C_j \leq d_l\}$
J_T	Set of tardy jobs scheduled to begin after or in d_r, $J_T = \{j \vert C_j - p_j \geq d_r\}$
J_W	Set of jobs that start and finish in the due window, $J_W = \{j \vert C_j - p_j \geq d_l \vee C_j \leq d_r\}$
s_l	Left-straddling job, $S_{s_l} < d_l \vee C_{s_l} > d_l$
s_r	Right-straddling job, $S_{s_r} < d_r \vee C_{s_r} > d_r$
s_d	Double-straddling job, $S_{s_d} < d_l \vee C_{s_d} > d_r$

guide the process of constructing a heuristic sequence. Despite the fact that an optimal schedule is V-shaped in each machine, it is essential to point out that it may contain one or two straddling jobs that are not necessarily subject to this property. We define a left-straddling job s_l if it straddles d_l, and right-straddling job s_r if it straddles d_r. Moreover, it is possible the existence of an optimal schedule with a double-straddling job s_d. In other words, a job that completely overlaps the common due window. From property 5, it also becomes evident that an optimal schedule might exist in which the first job does not start at time zero. We should call the time span before the starting of the first job as leading idle time.

3 Priority rules and greedy heuristic

Any algorithm designed for solving the PMSP with ET penalties subject to common due windows has two main decisions to address. The first one is how to assign jobs to machines, while the second concerns to the sequencing aspects on each individual machine. In this section, we establish a procedure devoted to find an initial schedule on each machine.

Rather than assigning each job to a machine without any predefined criteria, we decided to sort the jobs according to five different priority rules. These rules were established by Alvarez-Valdes et al [1] for a similar PMSP problem with

Algorithm 1: Greedy heuristic

```
1  Input: Initial job list (N) ;
2  Output: A schedule (π) ;
3  N ← {1, 2, ..., n}, M ← {M_1, M_2, ..., M_m}, flag ← true ;
4  Sort N according to one of the priority rules ;
5  while N ≠ ∅ do
6      if flag = true then
7          for i = 1 to m − 1 do
8              Let job in position [j] be the the first job in N ;
9              Assign job in position [j] to M_i ;
10             [j] ← [j + 1] ;
11         end
12         flag ← false ;
13     else
14         for i = 1 to m do
15             Insert jobs [j] and [j + 1] in every position of M_i ;
16             Save the best position in case of a minimum cost increase ;
17         end
18         Assign the job that produced the minimum cost increase to the best
             machine position ;
19         Update the first job of N ;
20     end
21 end
```

common due date. They tested several other rules, however, the following ones presented the best results:

- **Rule 1**: Nonincreasing $\beta_j p_j$.
- **Rule 2**: Nonincreasing $\beta_j p_j / \alpha_j$.
- **Rule 3**: Nonincreasing p_j.
- **Rule 4**: Nonincreasing β_j.
- **Rule 5**: Nondecreasing p_j / β_j.

Once the whole list of jobs is sorted, the jobs are assigned to each machine using a greedy heuristic. The first $m - 1$ jobs are distributed into the first $m - 1$ machines. Thereafter, the algorithm proceeds by promoting a competition between the next two jobs in the list. Calculations are made to determine in which machine and position the next two jobs attain a minimum cost increase. Then, the one that produces the minimum cost is assigned to the best position and the other is returned to the head of the list. The algorithm stops when the whole list is empty and the jobs are fully assigned to the machines. Algorithm 1 shows the pseudocode of the greedy heuristic.

4 Local search

The local search (LS) procedure was designed to exchange jobs between two machines that have different job charges. In other words, since the initial assignment do not consider the balance between earliness and tardiness penalties as well as processing times, LS looks for a decrease in the cost function by moving jobs from a machine to another. The following steps summarize the underlying idea of the LS and Algorithm 2 presents the pseudocode.

- Sort the machines in nonincreasing order of costs.
- Compute the total processing time (D_i^T), the sum of earliness penalties (α_i^T), and the sum of tardiness (β_i^T) penalties of each machine.
- Try to move all jobs $j \in M_i$ to all possible positions of M_{i+1} with a lower cost if at least one of the conditions holds: $D_i^T > D_{i+1}^T + p_j \vee \alpha_i^T > \alpha_{i+1}^T + \alpha_j \vee \beta_i^T > \beta_{i+1}^T + \beta_j$.
- If an improvement in the total cost is achieved, move job j from M_i to M_{i+1}.
- Repeat until all machines are tested.

Algorithm 2: Local Search

```
1  Input: Initial schedule (π) ;
2  Output: An improved schedule (π^new) ;
3  M ← {M_1, M_2, ..., M_m}, flag ← true ;
4  Sort the machines in nonincreasing order of costs ;
5  for i = 1 to m - 1 do
6      while flag = true do
7          Compute D_i^T, α_i^T, β_i^T, D_{i+1}^T, α_{i+1}^T, β_{i+1}^T ;
8          for all jobs j ∈ M_i do
9              if D_i^T > D_{i+1}^T + p_j ∨ α_i^T > α_{i+1}^T + α_j ∨ β_i^T > β_{i+1}^T + β_j then
10                 Try to move job j from M_i to M_{i+1} by inserting it in every
                    possible position ;
11                 Compute f(π^new) ;
12                 if f(π^new) < f(π) then
13                     Move job j to the best position in M_{i+1} ;
14                     flag ← true ;
15                 else
16                     Keep π unchanged ;
17                     flag ← false ;
18                 end
19             else
20                 flag ← false ;
21             end
22         end
23     end
24 end
```

5 Solving the single-machine subproblems

Once the jobs are distributed to machines, it is necessary to find better sequences on each machine. For this, two strategies are adopted: the RGH heuristic and SEA. Both deterministic methods are used to order the sequences on each machine. This is the third phase of the solution procedure. Hereafter, the nomenclature adopted to differentiate each solution procedure is RN-RGH and RN-SEA. Note that the nomenclature is followed by a number from 1 to 5, which distinguishes the 5 priority rules. The next two subsections describe these solutions procedures in detail.

5.1 RN-RGH

The RN-RGH algorithm is based on the procedure developed by Ying et al [20] for the single-machine problem with a common due window. The basic idea is to employ the constructive heuristic reported by these authors as an improvement method.

In a rather simplified manner, once the jobs are better distributed into the machines, their heuristic is applied in each machine separately. The algorithm starts by assigning the jobs that have high earliness and tardiness weights relative to their processing times to set J_W. Afterwards, from the remaining jobs, those which possess a high tardiness weight relative to the earliness weight are assigned to set J_E. Here, we omit the details of the algorithm due to space restrictions. For details and a numerical example we refer to Ying et al [20]. Again, their algorithm will be repeated in each machine and a new schedule will be constructed.

5.2 RN-SEA

The other improvement strategy is based on a Sequential Exchange Approach [14]. Here, a new heuristic is shown to schedule each machine against a common due window. Since there are three sets of jobs that constitute a solution for the problem (J_E, J_W, J_T), RN-SEA swaps or moves jobs between these sets systematically to derive a near-optimal solution. For the sake of simplicity, only two sets are considered since jobs in J_W may be sequenced in an arbitrary order. Now, let $J_{E'}$ denote the set of no-tardy jobs including the ones that start and finish in the due window ($J_{E'} = J_E \cup J_W$). Possible straddling jobs (s_l, s_r, and s_d) are also in $J_{E'}$ since they start processing before the right boundary of the due window.

For each machine, the jobs in $J_{E'}$ are selected one by one according to the sequence obtained as a result of phases one and two. This step is called forward exchange. The selected job $j \in J_{E'}$ is paired with all jobs in J_T to identify the swap which would lead to the largest improvement of the cost function value. Furthermore, job $k \in J_{E'}$ may move to J_T if this move leads to a greater improvement of the cost function than swapping jobs. If swapping the jth job in $J_{E'}$ with the lth job in J_T causes a better gain in the objective-function value than moving, the jth job in $J_{E'}$ and the lth job in J_T are swapped, while the

original sequences in $J_{E'}$ and J_T are maintained. On the other hand, if moving the kth job in $J_{E'}$ to J_T results in a best improvement than swapping, the kth job moves to J_T. After trying to swap or move all jobs in $J_{E'}$ to J_T, the best move is performed and the jobs are ordered according to the V-shaped property again.

The next step is called the backward exchange, which is similar to the forward exchange. However, jobs in J_T are selected one by one according to the sequence obtained from the previous step, and jobs are swapped with jobs in $J_{E'}$ to find the best improvement of the objective function value. Conversely, jobs in J_T are moved to $J_{E'}$ if the best improvement if a better gain is attained. After examining all the jobs in J_T to be swapped or moved to $J_{E'}$, the best move is performed and the final schedule is sequenced according to the V-shaped property once again.

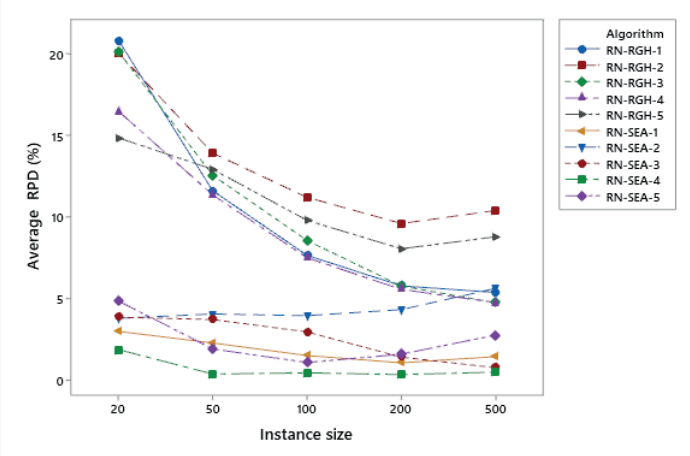
Since the common due windows are restricted in relation to the total processing time, the start time of the first job to be scheduled is set to be zero. Evidently, for instances where the left boundary (d_l) has a larger restrictive factor (h_l), it may be the case that possible straddling jobs should be eliminated to obtain better objective function values, therefore, the procedure identifies them and produces backward-shift solutions of right and left straddling jobs. The start time is calculated as $s_{[l]} = d_l - S_{s_l}$ and $s_{[l]} = d_r - S_{s_r}$. Of course, jobs should be rearranged according to the V-shaped property and the solution with the best objective function value is kept.

6 Experimental results

Since there is no heuristic reported for the problem under consideration, a numerical analysis is conducted between the 10 proposed algorithms. The experiments were conducted on a personal computer with an Intel® Core i5 processor running at 3.7GHz, 16GB of RAM, and implemented in C++ programming language. The benchmark instances are available at the well-known OR Library [1] [3]. The short Pascal generator as well as the problem instances were proposed for the analogous common due date single machine problem [4].

Table 2. Instance configuration

Factors	Levels
n	20, 50, 100, 200, 500
m	2, 4, 6
(h_l, h_r)	(0.1, 0.2), (0.1, 0.3), (0.2, 0.5), (0.3, 0.4), (0.3, 0.5)
α_j	$U[1, 10]$
β_j	$U[1, 15]$
p_j	$U[1, 20]$



[1] http://people.brunel.ac.uk/~mastjjb/jeb/info.html

The characteristics of the test set are seen in Table 2. We used 10 different instances from 5 sizes, 3 machine configurations and 5 restriction factors combinations. Therefore, each algorithm solved a total of $10 \times 5 \times 3 \times 5 = 750$ instances. Two central performance measures were adopted, namely, the relative percentage deviation (RPD) from the best solution (see Eq. 5) and the computing times.

$$\text{RPD}(\%) = \frac{\text{obj}^{\text{heu}} - \text{obj}^{\text{best}}}{\text{obj}^{\text{best}}} \tag{5}$$

In Eq. 5, obj^{heu} stands for the solution achieved by one of the heuristics and obj^{best} refers to the best solution found from all the heuristic approaches. Of course, small values of RPD indicate better solutions. To demonstrate the performance of the heuristics, the average RPD values are compared based on three factors that modify the characteristics of the problem: instance size; window configuration; and number of machines. Fig. 2 shows the relationship between average RPD and the instance size.

Fig. 2. Estimated marginal means of RPD according to instance size

There is a clear difference between the initial assignment rules as well as the sequencing strategy adopted for solving the single-machine subproblems. Clearly, the best performance is achieved for rule 4 (nonincreasing β_j) When comparing the results for the same sequencing strategies, that is, between the 5 rules using the same sequencing algorithm (RN-RGH or RN-SEA), this rule outperforms the others for almost all instance sizes, except when combined with RN-RGH for solving instances with $n = 20$. Such an effect may be explained due to the nature of the data of the test set. Note that the individual tardiness penalty is allowed to be greater than the earliness penalty (refer to Table 2). In most practical contexts, contractual penalties incurred by a tardy job is usually higher

than the cost of maintaining an early job in the inventory. Other possible explanation of the success of this rule relies on the fact that due windows are tight in relation to the sum of processing times. Following this rationale, a larger number of jobs should be scheduled in J_T, therefore, the amount of tardiness penalties is expected to be greater than the amount of earliness penalties. In terms of the improvements methods applied to sequence jobs in each machine, RN-SEA presented a consistently better performance. The reason for this behaviour relates to the fact that RN-RGH might lead to poor results if there are many jobs with $\beta_j \gg \alpha_j$, where α_j is near to one and d_l is relatively small: in this situation, probably not all jobs with high tardiness penalties can be processed prior to the common due window and hence accumulate higher tardiness costs.

Table 3. Average RPD (%) values according to m and window configuration.

Algorithm	m			Window (h_l, h_r)				
	2	4	6	0.1-0.2	0.1-0.3	0.2-0.5	0.3-0.4	0.3-0.5
RN-RGH-1	7.537	11.056	12.189	3.936	6.813	15.819	10.953	13.785
RN-RGH-2	10.548	13.831	14.746	3.970	7.331	20.941	12.240	20.727
RN-RGH-3	7.304	11.152	12.636	4.113	7.085	16.476	10.345	13.801
RN-RGH-4	7.069	9.354	10.968	3.747	6.250	13.755	9.507	12.391
RN-RGH-5	8.395	11.436	12.828	4.375	6.511	15.304	12.484	15.757
RN-SEA-1	1.831	1.936	1.835	0.523	1.017	3.106	2.054	2.637
RN-SEA-2	4.354	4.310	4.414	0.741	1.509	5.988	4.723	8.836
RN-SEA-3	2.203	2.363	3.084	0.695	1.671	4.623	2.543	3.219
RN-SEA-4	0.747	0.622	0.683	0.423	0.347	0.668	0.750	1.232
RN-SEA-5	1.435	2.661	3.161	0.474	0.655	2.524	3.682	4.761

Table 3 presents the RPD values according to the number of machines and window configuration. It is clear that RN-SEA-4 outperforms the other constructive algorithms in almost all situations. Note that the distance between the RPD values for more restricted windows reduces due to the fact that only few jobs belong to J_W or finish without being penalized. For larger windows, RN-SEA also performs better since it is capable of systematically exchanging jobs between sets and, consequently, finding better solutions.

To understand the differences between the means shown in Fig. 2 and Table 3, we conducted an Analysis of Variance (ANOVA) with a confidence level $\alpha = 0.05$ and RPD was set as the dependent variable [19]. Two hypothesis were tested:

- **H0**: The means of RPD are the same across all methods.
- **H1**: There are differences between the RPD means across the methods

Since the results indicated that the significance value for the test was 0.00, it is possible to conclude that at least one mean of the distributions of the RPD is different, therefore, the null hypothesis can be rejected. We omit the details of the test due to space restrictions.

Then, we utilized the *post-hoc* Tukey HSD test to identify which groups had different means. The sample size is equivalent to 750 per algorithm (number of solved instances). The homogeneous subsets are reported in Table 4. It is worth noting that the algorithms are ordered in increasing order of the means, i.e., group 1 presents a smaller RPD mean in comparison with group 2 and so on. Observe that the last row of the table indicates the significance value for each subset. Taking subset 1 as an example, the significance value is 0.072 which is greater than 0.05, hence, there is not a strong evidence that there are differences between the means from this group (the null hypothesis cannot be rejected).

Table 4. Homogeneous subsets

Algorithm	Subset for $\alpha = 0.05$					
	1	2	3	4	5	6
RN-SEA-4	0.007					
RN-SEA-1	0.019	0.019				
RN-SEA-5		0.024				
RN-SEA-3		0.026				
RN-SEA-2			0.044			
RN-RGH-4				0.091		
RN-RGH-1				0.103	0.103	
RN-RGH-3					0.104	
RN-RGH-5					0.109	
RN-RGH-2						0.130
Sig.	0.072	0.764	1.000	0.104	0.845	1.000

Finally, other important measure refers to the computing efforts applied to obtain the solutions previously discussed. When the heuristics are compared in terms of the sequencing strategy on each machine, it is observed that the family of RN-RGH heuristics requires less computational effort in relation to RN-SEA. This type of behaviour occurs specially when the number of jobs exceeds 200, i.e., comparing two heuristics with the same initial assignment rules such as RN-RGH-3 and RN-SEA-3, it is seen that the average computing time of RN-RGH-3 for instances with 500 jobs is far inferior to the one in RN-SEA-3.

Moreover, as the number of machines increases, the computing times tend to decrease. Such a counter-intuitive result is also consistent with other studies in the same field [6, 7]. The cause of this effect may relate to the smaller number of jobs assigned to each machine, which may reduce the number of combinations tested by the heuristics. In contrast with the instance size and the number of machines, the window configuration does not seem to alter the computing times. Table 5 summarizes the average CPU times in seconds according to instance size and number of machines.

Table 5. Average CPU times in seconds (s)

Algorithm	n					m		
	20	50	100	200	500	2	4	6
RN-RGH-1	> 0.00	> 0.00	> 0.00	0.04	1.18	0.53	0.15	0.06
RN-RGH-2	> 0.00	> 0.00	> 0.00	0.06	1.91	0.87	0.24	0.09
RN-RGH-3	> 0.00	> 0.00	> 0.00	0.08	2.75	1.29	0.31	0.11

RN-SEA-5	> 0.00	> 0.00	0.01	0.09	3.41	1.72	0.28	0.11

7 Concluding remarks

In this paper, we have developed a family of ten heuristics for scheduling parallel machines subject to common restrictive due windows. The results were evaluated between the heuristics due to the fact that there is no other similar approach for the same problem. As a matter of fact, only Chen and Lee [6] proposed some exact solution procedures, however, they report that only instances with up to 40 jobs in size can be solved in reasonable time. Actually, their algorithms are quite complex and require a lot of implementation efforts from a computational perspective, therefore, our objective was to develop easy implementation algorithms capable of solving instances with up to 500 jobs in size. Our computational studies confirm that the most time consuming heuristic have an average CPU time of approximately 80 seconds, which confirms the possibility of application in practical contexts. In general, RN-SEA family has a better performance in relation to RN-RGH, however, higher CPU times are expected. For both RN-SEA and RN-RGH families, the fourth priority rule performs better, which can be justified according to the structure of the data used as a test set. Clearly, instances generated using a different range of values may benefit other priority rules.

One line of future research, would be to take advantage of designing parallel or cooperative algorithms. Moreover, a mathematical model could be implemented for solving small-sized instances. This way, further comparisons could be conducted with the heuristics shown in this paper and benchmarks reporting the lower bounds could be proposed. Another line of research would be the extension of this study to other related problems, such as the case of distinct due windows, sequence-dependent setup times, inclusion of release dates, different machine environments, etc.

Abstract. The Online Lot Streaming (OLS) problem is introduced and tackled by a Constraint Programming (CP) approach. It is addressed at a Flexible Job Shop environment. In the OLS problem, lot streaming activities are performed dynamically and recursively, on an ongoing agenda. This is a novel approach, which differs from the predictive LS one. In this proposal, an OLS activity is also presented as a valid adaptive/reactive action. A test problem result is depicted to show the main characteristics of the solution.

Keywords: Online Scheduling, Lot Streaming, Rescheduling Problem.

1 Introduction to Online Lot Streaming Problem

The rescheduling problem and the lot streaming (LS) problem are two challenges that have received a lot of attention from the academic community and practitioners.

On the one hand, and so far, the reactive actions performed to adapt a disrupted schedule were implemented as tasks movements forward or backward in the agenda, tasks swaps or interchange, reallocation of resources to tasks, tasks cancelations and insertions, among the most usual ones (Vieira et al., 2003). On the other hand, contributions about the lot streaming problem, have addressed this activity as a predictive operational action, intended to split already dimensioned lots into smaller sublots, at the beginning of a given scheduling horizon. (Chan & Chiu, 2005).

In this work, a lot with an already defined and in-progress agenda, is enabled to be split downstream in the process, as a feasible reactive or adaptive action. In fact, the lot streaming as an allowed reactive action can be applied not only as a repair action to a disrupted agenda, but an adaptation action when the planned schedule underperforms.

The present approach is developed considering the scheduling as an online activity. Thus, scheduling activities are carried out considering a rolling horizon policy and using knowledge from the domain and the agenda status. Every time the MES concludes that the in-progress agenda needs an adaptation, it is carried out considering the current and known data coming from the shop floor. Here, a schedule adaptation refers to (i) a required rescheduling activity caused by an unexpected event, (ii) a

modification of the agenda caused by deviations from what has been planned, or, (iii) an action based on the chance of performance improvement. This work addresses the problem of lot streaming as an online activity. The *Online Lot Streaming* (OLS) problem is concerned with LS decisions, but performed dynamically on an ongoing agenda, over tasks that are planned or under execution when the LS activity is carried out. In this proposal, the OLS problem is tackled at flexible job shop environments.

2 An OLS Approach

The proposed approach requires the characterization of (i) the lot entity, (ii) the ongoing agenda features, and (iii) the OLS adaptive process. This enables a proper development of a constrained programming-based (CP) model, capable of addressing the ongoing situation being solved.

Characterization of lots. Lots *i* are associated with a single job or production order *j*, which elaborates a single product. The original sizes of the lots are defined upstream, at planning level by lot-sizing techniques (which differs from the operational LS problem), so they are known in advance. It is worth noting that, as online activity, lots are enabled to be divided during an ongoing agenda.

From the division of a lot, two or more sublots are created. For simplicity reasons, the sublots will be hereafter referred as lots too. The way they are generated and further divided during the process is represented by a tree structure. The *j* lots tree structure is neither predefined nor static, but dynamically generated for each lot during execution, when it is needed. Thus, the tree representation exists while there is at least one lot *i* being manufactured, associated with job *j.* Each lot *i* of *j* exists for a given period, called the lot *i* lifetime. A *j*'s lots tree is composed of any number of created lots, which were generated through time, during the manufacturing process, in order to complete all the operations required for all the parts belonging to the demanded job *j*.

It is considered that each lot has an identity on the schedule since it is created until it is further split or, until its manufacturing is completed, i.e. when a lot is divided, its existence ends, and new lots are created from it (see **¡Error! No se encuentra el origen de la referencia.**).

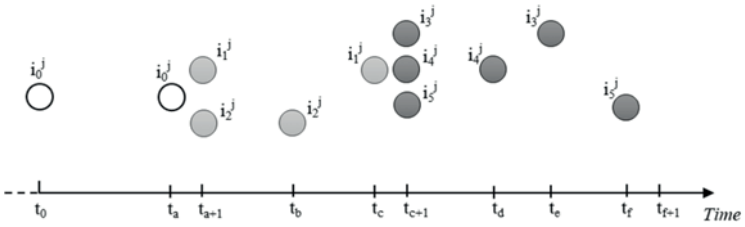

Fig. 1. Job *j* lots tree life representation. The lots i_1^j and i_2^j are child lots from their parent lot i_0^j.

The tree representation allows to identify the lots as: (i) *Original lot*, (ii) *Parent lots*, and (iii) *Child lots.* The child lots are created from a parent one and have a different identity than its parent. The proposed OLS differs from the problems classified as variable sublot, since in that case the sublot maintains its identity while it can vary its size during the planned agenda and there is no split during the schedule execution.

Ongoing agenda characterization. In the previous section, the dynamic behavior of lots were defined independently of the operations that they are planned to receive. However, there is a relation: when a lot *i* associated with a job *j* requires an operation *o*, a production task a is scheduled to accomplish that activity.

Each task *a* has its own attributes, which can vary over time. Each time t_c the agenda is observed, its status is captured; i.e. all entities belonging to the domain are asked for their attribute's current values. Afterwards, a classification is carried out.

Tasks & lots classification. At each t_c: (i) Tasks in the agenda are classified in already executed tasks, in progress tasks, and not yet executed tasks (Novas & Henning, 2010). The present proposal focuses on the in-progress tasks and the ones not executed yet. (ii) Lots are classified in those requiring to be divided (for instance, when an operation on a lot is interrupted), those that are enabled to split, but it is not a mandatory action, and the ones that are forbidden to be divided.

OLS process characterization. All features requiring to be addressed are identified, as well as all the preprocessing data activities. For instance, if a lot under an ongoing given operation was interrupted and requires to be divided, there will be parts belonging to that lot that still need the operation, and another number of parts that requires to schedule the next operation.

A CP model for the OLS. The proposal is presented as a constrained-based formulation, implemented as a Constraint Programming (CP) model, which was elaborated on the IBM ILOG CPLEX Optimization Studio. The approach is based on the CP model presented in Novas (2019) for the LS & Scheduling problem and extended for the OLS. Constraints and expressions are classified in those required to capture the domain status at a given time point, the ones linked to the adaptive action, and those to schedule and optimize. The complete model is not presented here because of the lack of space.

3 A Test Case Study

Here, a single example is depicted for illustrative purposes. An ongoing agenda in a 5 machines FJS, is under execution: 3 jobs, 3 operations per job, 2 lots for *j*1, 3 lots for *j*2 and *j*3 (Fig. 2 (a)). At time t_c =2500 s, the agenda is revised for 100 *s*. As it can be observed in Fig. 2(b), at t_u =2600, a new schedule is proposed for the rest of the schedule horizon. Fig. 2(c) shows the lots tree of *j*3 observed once the complete number of parts demanded by *j*3 is finished.

The split at t_c of several lots, results in a new agenda from t_u, which reaches a better makespan than the original one (original mk=6785; new mk=6535). These results illustrate how the OLS as a reactive/adaptive action can also be a powerful tool to dynamically improve the performance of an ongoing agenda.

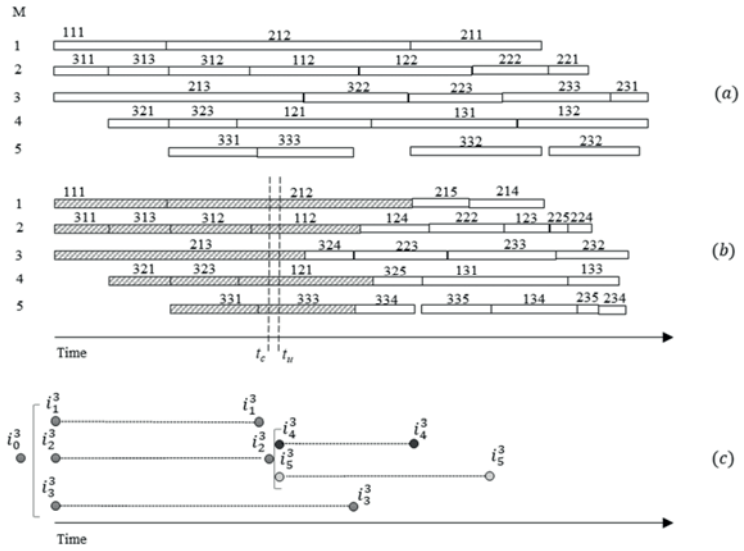

Fig. 2. (a) Gantt chart depicting the predictive ongoing agenda. Tasks' labels represent the job, operation and lot numbers. (b) New agenda for remaining tasks from t_u. (c) The job $j3$ lots' tree.

4 Conclusions

The Online Lot Streaming (OLS) problem was introduced for the first time and an approach to characterize it was proposed. The main features describing the OLS problem were presented and a CP model was developed to solve it. An illustrative example is depicted.

Resumen. En este trabajo se propone una metodología que integra a la Programación por Metas Ponderadas con el Proceso Analítico de Jerarquías para la obtención de la mezcla de productos, en un sistema de múltiples cuellos de botella. Se aborda el problema analizando un caso adaptado de una empresa que fabrica 4 productos que deben pasar por 6 estaciones de trabajo. Se considera la opinión de 4 expertos involucrados en la decisión y se plantean metas que consideran maximización del beneficio, la explotación de los recursos cuellos de botella y la satisfacción del cliente. La priorización de dichos objetivos se obtiene a través del Proceso Analítico de Jerarquías, donde se agrega la opinión de los expertos y se obtiene un único vector, que se transforma en las ponderaciones de las metas. El resultado es una mezcla de producción que satisface las metas, en forma correspondiente a la opinión de los expertos.

Palabras Clave: Programación por Metas. Proceso Analítico de Jerarquías. Juicios Agregados.

1 Introducción

En trabajos anteriores se ha analizado el caso de una empresa cuyo sistema de producción tenía una capacidad tal que no lograba satisfacer la totalidad de la demanda pronosticada [1]. Para la resolución del mismo se planteó en principio el clásico modelo de programación lineal. Este modelo arrojó una mezcla para la cual se obtuvo el máximo beneficio. Pero como suele suceder, al momento de realizar la planificación de la producción el decisor puede tener que considerar otros objetivos, además, de obtener el máximo beneficio. Estos objetivos pueden estar ligados a las prioridades competitivas, a eventualidades propias del sistema de producción tales como la disminución del rendimiento de alguno de los recursos, entre otros. En dicho estudio, se propuso la aplicación de un modelo de Programación por Metas Ponderadas que brindó flexibilidad, permitiendo acercarse a una solución que se ajustó mejor al entorno del sistema. Dicha solución varió en función del peso o ponderación que se les otorgó a las variables de desviación. Este resultado permitió comprender que si estas ponderaciones están debidamente sustentadas la solución se puede considerar mucho más sólida.

En el presente trabajo, se propone aplicar una metodología para tomar la decisión de obtener la mezcla de productos, que permita alcanzar varios objetivos, en función de lo que se considere prioritario, siendo esta prioridad definida a partir de la aplicación del proceso Analítico de Jerarquías.

La estructura del trabajo es la siguiente:

En la próxima sección se presenta el marco teórico y la revisión bibliográfica que permitieron el análisis y propuesta de una metodología válida a la problemática planteada.

En la sección de desarrollo se presentan las principales características de la organización tales como relevamiento del proceso, recursos de la producción, costos y demanda pronosticada. A partir de los mismos se prueba la metodología propuesta y se plantean las soluciones halladas.

Finalmente se hace un análisis de resultados y conclusiones.

2 Marco Teórico

La Programación por Metas (PM) fue propuesta por Charnes y Cooper en 1961 como un método sencillo para resolver los problemas lineales de programación multiobjetivo que eran infactibles. Desde entonces se han desarrollado numerosos trabajos que abordan tanto los aspectos teóricos como los operativos de la técnica, abarcando un amplio campo de aplicación [2].

La PM es para Tamiz, Jones y Romero [3] "una metodología flexible y pragmática especialmente adecuada para resolver problemas con variables decisionales complejas en los que diversos objetivos al igual que muchas de las variables y de las restricciones, están involucrados".

Buscar lo "aceptable" antes que lo "óptimo" constituye el lema de esta técnica, siendo su objetivo final llegar a encontrar una solución que satisfaga las necesidades. Filosóficamente la PM se apoya en el concepto de soluciones "satisfacientes", introducido por Herbert Simon [4]. El término satisfaciente intenta fusionar los términos "satisfactorio" y "suficiente" [5]. En otras palabras, el decisor intenta obtener una solución que se aproxime, en lo posible, a unos niveles de satisfacción denominados "niveles de aspiración" que han sido prefijados de antemano para cada uno de los objetivos. La "mejor" solución, (solución satisfaciente), se define en PM como aquélla que minimiza las desviaciones no deseadas del conjunto de objetivos o niveles de aspiración.

2.1 Estructura formal de los modelos de PM

Los objetivos múltiples y en conflicto, las restricciones y las metas son elementos característicos de los modelos de PM. Dentro de este contexto, las "metas" representan las restricciones no rigurosas que el decisor desea que se satisfagan, pero que al mismo tiempo pueden ser violadas en caso de no existir puntos que las verifiquen, considerándose a estas soluciones como admisibles.

En PM los objetivos se transforman en restricciones meta, las que se añaden al conjunto de restricciones fijas, propias del sistema. Las restricciones meta representan limitaciones no rigurosas, debido a que el nivel de aspiración deseado puede ser o no

alcanzado. Para ello, se precisa introducir variables de desviación positivas (p_i) y negativas (n_i), que midan en cada instante el exceso o la falta de cumplimiento de cada meta con respecto al nivel de aspiración deseado.

Para tratar de alcanzar el nivel de logro requerido se debe minimizar una función de las desviaciones no deseadas. A este arreglo se lo denomina funcional. Una variable de desviación se dice no deseada cuando se necesita que alcance su valor más pequeño, preferentemente cero. Se pueden presentar tres posibilidades:

- La meta debe alcanzar el mayor nivel de aspiración de un atributo, $f_i(x) \geq t_i$. En este caso la variable no deseada será la n_i.
- La meta espera el menor valor de un atributo, $f_i(x) \leq t_i$. En este caso la variable no deseada será la p_i.
- La meta pretende alcanzar exactamente el nivel de aspiración, $f_i(x) = t_i$ las variables no deseadas son n_i y p_i.

La estructura general de un modelo de PM con "q" metas, "m-q" restricciones del sistema o restricciones técnicas y "n" variables decisionales se presenta en Ecuaciones 1 a 4 [6], [7]:

Modelo General de PM

Función de logro

$$\min Z = g(n_i, p_i) \tag{1}$$

Sujeto a:

$$f_i(x) + n_i - p_i = t_i \quad \forall\, i \in \{1, \ldots, q\} \quad (\text{metas}) \tag{2}$$

$$h_i(x) \leq b_i \quad \forall\, i \in \{q+1, \ldots, m\} \quad (\text{restricciones}) \tag{3}$$

$$x, n_i, p_i \geq 0 \tag{4}$$

Donde:

n_i, p_i = desviaciones negativas y positivas, que cuantifican la falta o exceso de logro respectivamente;

$X = (x_1, x_2, \ldots, x_j) \in \Re n$ vector de variables de decisión

t_i = nivel de aspiración asociado al atributo i-ésimo.

En Ecuación 5 se representa la expresión matemática de $f_i(x)$ o $h_i(x)$

$$f_i(x) \text{ o } h_i(x) = \sum_{j=1}^{n} a_{ij}\, x_j \quad \forall\, j \in \{1, \ldots, n\} \tag{5}$$

Las variables de desviación negativa (n_i) y positiva (p_i) de la meta i-ésima están definidas algebraicamente en Ecuaciones 6 y 7:

$$p_i = \max\{0, f_i(x) - t_i\} \quad \text{ó} \tag{6}$$

$$p_i = \frac{1}{2}[|f_i(x) - t_i| + f_i(x) - t_i]$$

$$n_i = \max\{0, t_i - f_i(x)\} \quad \text{ó} \tag{7}$$

$$n_i = \frac{1}{2}[|f_i(x) - t_i| + t_i - f_i(x)]$$

De acuerdo con Tamiz, Jones y El-Darzi [8], Ignizio y Romero [9] y Romero [10], la función de logro detallada en ecuación 1, puede tomar diferentes configuraciones, dando origen a distintos modelos de PM. Entre los modelos más tradicionales, se pueden mencionar los siguientes:

(i) minimizar la suma ponderada de todas las desviaciones no deseadas en forma simultánea, llamado Programación por Metas Ponderadas;

(ii) minimizar las desviaciones no deseadas por orden de importancia y en un sentido lexicográfico, denominado Programación por Metas Lexicográficas;

(iii) minimizar únicamente la desviación más grande en el sentido min-max, conocido como Programación por Metas Minimax o Chebyshev.

En la próxima sección, se desarrolla brevemente el modelo mencionado en i) dado que es el que aplica a la metodología propuesta.

Programación por Metas Ponderadas (PMP)

La PMP también conocida como programación por metas arquimediana, busca minimizar el logro agregando las metas en una única función. Para este caso la ecuación 1 queda determinada por la Ecuación 9. Las ecuaciones 2 a 4 correspondientes a las restricciones, presentadas en el modelo general, no sufren modificaciones [7]

$$min\left(\sum_{1=1}^{q} \alpha_i\, n_i + \beta_i p_i\right) \tag{8}$$

Siendo:

$\alpha_i = w_i/k_i$, si n_i es no deseada; en caso contrario $\alpha_i = 0$;

$\beta_i = w_i/k_i$, si p_i es no deseada; en caso contrario $\beta_i = 0$;

w_i = pesos de ponderación o de preferencia;

k_i = constantes de normalización

Los pesos w_i permiten diferenciar los distintos objetivos en orden de importancia; valores mayores representan metas más importantes.

Los objetivos inconmensurables deben ser tratados en términos de una misma unidad de medida. Por ello, es necesario afectarlos por una constante de normalización. Se pueden emplear diferentes constantes de normalización, las más utilizadas son:

- El valor objetivo o target $k_i = t_i$, (no es aplicable cuando los objetivos son cero)
- La norma Euclideana, de los coeficientes técnicos del objetivo a_{ij} (ver Ecuación 9)

$$k_i = \sqrt{\sum_j {a_{ij}}^2} \tag{9}$$

- La sumatoria de los valores absolutos de los coeficientes técnicos del objetivo (ver Ecuación 10)

$$k_i = \sum_j |a_{ij}| \tag{4}$$

El Proceso Analítico de Jerarquías.

El Proceso Analítico de Jerarquías (PAJ) (o AHP, Analytic Hierarchy Process), desarrollado por Thomas L. Saaty, [11] está diseñado para resolver problemas complejos que tienen criterios múltiples.

Es un método de trabajo sencillo, lógico y estructurado, basado en la descomposición del problema en una estructura jerárquica.

Parte del proceso requiere que quien toma las decisiones proporcione evaluaciones objetivas y/o subjetivas respecto a la importancia relativa de cada uno de los criterios que se seguirán para tomar la decisión. Se utilizan matrices de comparaciones pareadas para establecer dichas preferencias. Las comparaciones pareadas son las bases fundamentales del PAJ. Se emplea la escala de Saaty con valores de 1 a 9, como se muestra en Tabla 1, para calificar las preferencias relativas de los elementos. A través de un desarrollo matemático se calculan los vectores de prioridades.

Tabla 1. Escala de Saaty.

Planteamiento verbal de la preferencia	Calificación Numérica
Extremadamente preferible	9
Entre muy fuertemente y extremadamente preferible	8
Muy fuertemente preferible	7
Entre fuertemente y muy fuertemente preferible	6
Fuertemente preferible	5
Entre moderadamente y fuertemente preferible	4
Moderadamente preferible	3
Entre igualmente y moderadamente preferible	2
Igualmente preferible	1

Una consideración importante en términos de la calidad de decisión final se refiere a la consistencia de juicios que muestra el tomador de decisiones en el transcurso de la serie de comparaciones pareadas. La consistencia perfecta es difícil de lograr ya que los juicios son realizados por personas. Esta metodología calcula la relación o razón de consistencia de Saaty, RC, considerando aceptable los valores menores a 0,1. Si el grado de consistencia es aceptable, puede continuarse con el proceso de decisión. Si dicho grado es inaceptable, quien toma las decisiones debe reconsiderar y modificar sus juicios sobre las comparaciones pareadas antes de continuar con el análisis. Este procedimiento asegura la no existencia de inconsistencias en la emisión de juicios.

Otra consideración, también de suma importancia, es que esta metodología permite la introducción de juicios de los diversos actores que pudieran intervenir en la decisión. Cuando se plantean los juicios de dos o más expertos, existen básicamente dos modos filosóficos distintos de agregar la información individual. La elección va a depender si el grupo quiere actuar en conjunto o en forma separada, Forman y Peniwati [12]. Uno de los modos consiste en trabajar con el grupo en conjunto formando uno nuevo a partir

de la agregación de los juicios individuales (AIJ) en cada nivel de la jerarquía. Esto produce la pérdida tanto de identidad como de las preferencias individuales de los participantes a favor de una combinación sinérgica, que actúa como única. Dicha combinación debe satisfacer la condición de reciprocidad de los juicios. Saaty [11] propone la utilización de la media geométrica como la única forma de sintetizar en un solo juicio representativo las opiniones de todos los participantes en la toma de decisiones.

El otro modo, es cuando los participantes actuando en forma separada con distintas valoraciones del sistema, desean mantener su independencia e identidad. En este contexto, el proceso de agregación se realiza al final, una vez obtenidas las prioridades individuales (AIP). Dicha combinación se puede realizar tanto a través de la media aritmética (representativa de un intervalo promedio) o media geométrica (representativa de un cociente promedio). Forman y Peniwati [12] sostienen que la media geométrica es una medida consistente, ya que en el PAJ se utilizan escalas de razón, donde se evalúa cuantas veces es más preferible una alternativa frente a otra.

2.2 Metodología propuesta

A partir de los datos de la empresa se evalúan los objetivos que se desean cumplir, en función del entorno de la organización. Utilizando el Proceso Analítico de Jerarquías, se obtiene el vector de prioridades que sintetiza la opinión agregada de 4 expertos, en forma sistemática. Las preferencias representan la importancia relativa que tienen los objetivos considerados.

Este vector resultante, se ingresa en el modelo de programación por metas como la ponderación de las desviaciones, afectando de esta forma la composición de la mezcla.

Se utiliza Excel y su complemento Solver, tanto para PAJ como para la programación por metas.

Cabe destacar que los datos reales se adecuaron para explicar con mayor claridad la metodología propuesta.

3 Desarrollo

En la siguiente sección, se presentan las principales características técnico-económicas de la organización. Seguidamente se plantea como primera alternativa de mezcla de producción a la solución que es arrojada por el modelo de Programación Lineal. Los resultados de este modelo, que en cierta forma revelan el comportamiento del sistema de producción ante la demanda impuesta, son sometidos a juicio de los distintos departamentos involucrados en la decisión. Como consecuencia, ~~se~~ proponen diversos objetivos a cumplir por la solución buscada.

Estos objetivos son evaluados por los expertos de cada departamento, aplicando el Procesos Analítico de Jerarquías, generándose una matriz de comparaciones pareadas para cada uno de ellos. Se utiliza la agregación de los juicios individuales, AIJ, a efectos de integrar todas las opiniones en un único vector.

Finalmente, los resultados de este proceso se introducen en el modelo de Programación por Metas Ponderadas.

3.1 Descripción de la organización

La empresa fabrica y vende 4 productos, denominados X_1, X_2, X_3 y X_4.

En la Tabla 2 se detallan los procesos que se desarrollan como así también los medios de transporte interno utilizados para llevar los materiales de un sector a otro:

Tabla 2. Procesos de obtención de los productos.

Operación	Proceso	Transporte interno
1	Descarga	Autoelevador
2	Almacenamiento	Autoelevador a estanterías
3	Ensamble	Carro manual a puesto ensamble
4	Pintura	Carro manual a puesto pintura
5	Empaque	Riel de ganchos a sector empaque
6	Despacho	Autoelevador

Características técnico-económicas del sistema

En la Tabla 3, se muestran los datos brindados por el área de Finanzas, referidos al costo y beneficio unitario, como así también aquellos provenientes del área de Comercialización, en este caso, precio de venta y demanda proyectada.

Tabla 3. Datos de Comercialización y Finanzas

	X_1	X_2	X_3	X_4
PV	1850	1730	1950	1600
Costo [$/u]	1.011,25	844,13	870	1.147,5
Beneficio [$/u]	838,75	885,88	1080	452,5
Demanda [u/mes]	800	450	500	600
Beneficio total [$/mes]	671.000	398.643,75	540.000	271.500

Se espera un beneficio total de $1.881.143,75, si se fabrica toda la demanda.

En Tabla 4 se presentan las capacidades de las actividades correspondiente al sistema de operaciones de la organización y en la Tabla 5 los requerimientos por producto.

Tabla 4. Capacidad de las actividades.

Actividad	N° de operarios	h/mes
DESCARGA (DC)	4	640
ALMACENAMIENTO (AL)	1	160
ENSAMBLE(EN)	12	1920
PINTURA (PI)	8	1280
EMPAQUE (EQ)	6	960
DESPACHO (DP)	4	640

Tabla 5. Consumo de las actividades según el producto.

Actividad	X_1[h/u]	X_2[h/u]	X_3[h/u]	X_4[h/u]
DESCARGA (DC)	0,33	0,283	0,5	0,025
ALMACENAMIENTO (AL)	0,0167	0,025	0,005	0,04
ENSAMBLE(EN)	0,49	0,361	0,32	0,56
PINTURA (PI)	0,65	0,25	0,42	0,68
EMPAQUE (EQ)	0,65	0,68	0,74	0,62
DESPACHO (DP)	0,6	0,6	0,45	0,3

Finalmente, en Tabla 6, se presenta el análisis de la capacidad de la instalación en función de la demanda proyectada.

Tabla 6. Consumo de los recursos para la demanda proyectada.

Act.	X_1	X_2	X_3	X_4	h. nec	h. disp.	%utilización
DC	266,7	127,5	250,0	15,0	659,2	640,0	103,0
AL	13,3	11,3	2,5	24,0	51,1	160,0	31,9
EN	392,0	162,5	160,0	336,0	1050,5	1920,0	54,7
PI	520,0	112,5	210,0	408,0	1250,5	1280,0	97,7
EQ	520,0	306,0	370,0	372,0	1568,0	960,0	163,3
DP	480,0	270,0	225,0	180,0	1155,0	640,0	**180,5**

Se observa que los recursos DC, EQ Y DP se encuentran sobrecargados si se desea satisfacer la totalidad de la demanda. Es decir, que se está en presencia de un sistema de múltiples cuellos de botella. El requerimiento más crítico es el correspondiente a la actividad de DP.

3.2 Obtención de la mezcla óptima (de máximo beneficio)

A partir de los datos presentados, se aplica el modelo de Programación Lineal (PL), a efectos de obtener la mezcla que maximiza el beneficio, utilizándose el complemento Solver de Excel.

Los resultados obtenidos para PL son:

- La mezcla que optimiza el beneficio está formada por 27 unidades de X_1, 450 de X_2, 500 de X_3 y 429 de X_4.
- El beneficio alcanzado por la fabricación y venta de esta mezcla es de $ 1.144.412,5
- Los recursos EQ y DP son los que más se utilizan, y prácticamente se han agotado.
- El recurso DC emplea 397,55 h.

Estos resultados son observados por los distintos expertos involucrados en la decisión, tal como se detalla a continuación:

- El Experto I, del Departamento de Finanzas, si bien comprende la insuficiente capacidad de fabricación, observa que con esta mezcla se alcanza el 61% del beneficio total posible de alcanzar con la demanda requerida;
- El Experto II, del Departamento de Operaciones, sostiene que no es deseable que las operaciones cuello de botella queden con horas ociosas;
- El Experto III, del Departamento de Recursos Humanos, observa la operación DC tiene asignados 4 operarios, al igual que la operación DP. Las horas ocupadas de DC alcanzan un 62% mientras que las de DP son casi el 100%. Esto revela un desbalanceo en el contenido de trabajo entre ambas operaciones, que en principio y dada su especialización, son regidas por el mismo convenio laboral (reciben la misma paga). Esta situación puede generar un entorno de trabajo insatisfactorio que afecte incluso, a toda la organización.
- El Experto IV, del Departamento de Comercialización, observa que sería importante que demanda de X_1 y X_2 sea satisfecha en un 100% dada la importancia del cliente.

Considerando estas observaciones se aplica el Modelo de Programación por Metas Ponderadas (PMP).

3.3 Aplicación de Modelo de Programación por Metas Ponderadas

Considerando las observaciones de los expertos, se definen las siguientes metas:

1. maximizar el beneficio
2. maximizar el uso del recurso DC a efectos de disminuir el desbalanceo entre puestos de trabajo similares;
3. maximizar la explotación de los cuellos de botella EQ y DP dado que son los recursos que restringen el sistema
4. satisfacer la totalidad de la demanda de X_1 y X_2

En consecuencia, se plantean las siguientes restricciones meta (ver Ecuaciones 12 a 17):

Meta 1: obtención del máximo beneficio:

$$838{,}75\,\mathbf{X_1} + 885{,}875\,\mathbf{X_2} + 1080\,\mathbf{X_3} + 452{,}5\,\mathbf{X_4} + \mathbf{n_1} = 1.881.143{,}75 \quad (5)$$

Meta 2: maximizar el uso del recurso DC

$$0{,}33\,\mathbf{X_1} + 0{,}283\mathbf{X_2} + 0{,}5\,\mathbf{X_3} + 0{,}025\,\mathbf{X_4} + \mathbf{n_2} = 640 \quad (6)$$

Meta 3: maximizar el uso del recurso EQ y DP

$$0{,}65\,\mathbf{X_1} + 0{,}68\,\mathbf{X_2} + 0{,}74\,\mathbf{X_3} + 0{,}62\,\mathbf{X_4} + \mathbf{n_3} = 960 \quad (7)$$

$$0{,}6\,\mathbf{X_1} + 0{,}6\,\mathbf{X_2} + 0{,}45\,\mathbf{X_3} + 0{,}3\,\mathbf{X_4} + \mathbf{n_4} = 640 \quad (8)$$

Meta 4: fabricar toda la demanda de x_1 y x_2

$$\mathbf{X_1} + \mathbf{n_5} = 800 \quad (9)$$

$$\mathbf{X_2} + \mathbf{n_6} = 450 \quad (10)$$

Se proponen 2 modelos distintos. En el primer modelo, se analiza el resultado de no establecer preferencia alguna entre las metas a cumplir.

En el segundo modelo, se introducen las preferencias entre los distintos expertos, para cumplir con las metas.

PMP con metas normalizadas e igualmente ponderadas (PMN)

En este caso, el funcional responde a la siguiente expresión, Ecuación 18:

$$\text{Min } z = g(n_1, n_2, n_3, n_4, n_5, n_6) \quad (11)$$

- ✓ Las restricciones metas son las que se presentan en ecuaciones 12 a 17
- ✓ Las restricciones de capacidad del sistema, se muestran en las Ecuaciones 19 a 21:

$$\text{Hs AL} \quad 0{,}017\,X_1 + 0{,}025\,X_2 + 0{,}005\,X_3 + 0{,}04\,X_4 \leq 160 \quad (12)$$

$$\text{Hs EN} \quad 0{,}49X_1 + 0{,}361X_2 + 0{,}32X_3 + 0{,}56X_4 \leq 1920 \quad (13)$$

$$\text{Hs PI} \quad 0{,}65X_1 + 0{,}25X_2 + 0{,}42X_3 + 0{,}68X_4 \leq 1280 \quad (14)$$

$X_j \geq 0$ y entero

- ✓ Las restricciones de demanda, se visualizan en las Ecuaciones 22 y 23:

$$X_3 \leq 500 \quad (15)$$

$$X_4 \leq 600 \quad (16)$$

Los coeficientes de las desviaciones se normalizan, dividiendo los mismos por su función objetivo

Utilizando el complemento Solver de Excel, se obtienen los siguientes resultados para PMN:

- la mezcla está formada por 242 unidades de X_1, 449 de X_2, 500 de X_3 y 1 de X_4.
- El beneficio obtenido es de $ 1.141.187,88.
- El recurso DC utilizado 413,16h h.
- El recurso EP utilizado es de 959,63 h.
- El recurso DP utilizado es de 639,9 h.

Programación por Metas Ponderadas según criterio del decisor (PMAIJ)

Para la ponderación de los criterios se utiliza una matriz de comparaciones pareadas que permite al decisor determinar la importancia relativa de las desviaciones no deseadas. Se definen:

C_1: coeficiente que pondera el beneficio
C_2: coeficiente que pondera explotación de DC
C_3: coeficiente que pondera explotación de EQ
C_4: coeficiente que pondera explotación de DP
C_5: coeficiente que pondera las ventas de X_1

C_6: coeficiente que pondera las ventas de X_2

En las Tablas 7 a 10 se presentan las matrices de comparaciones pareadas arrojadas por los distintos expertos. Las ponderaciones se realizaron utilizando la escala de Saaty.

Tabla 7. Comparación pareada de los coeficientes Experto I.

	C_1	C_2	C_3	C_4	C_5	C_6
C_1	1	6	6	6	3	3
C_2	0,167	1	1	1	1	1
C_3	0,167	1	1	1	1	1
C_4	0,167	1	1	1	1	1
C_5	0,333	1	1	1	1	1
C_6	0.333	1	1	1	1	1

Tabla 8. Comparación **pareada de los coeficientes Experto II.**

	C_1	C_2	C_3	C_4	C_5	C_6
C_1	1	0,111	1	1	1	1

Se calcula RC = 0,00083 verificando de esta forma, la consistencia de la matriz.

Los componentes del vector resultante, se normalizan y se introducen en el modelo de PMP.

Utilizando el complemento Solver de Excel, y se obtienen los siguientes resultados para PMAIJ:

- la mezcla está formada por 616 unidades de X_1, 449 de X_2, 2 de X_3 y ninguna de X_4.
- El beneficio obtenido es de $ 916.587,88
- El recurso DC utilizado 333,55 h.
- El recurso EP utilizado es de 707,2 h.
- El recurso DP utilizado es de 639,9 h.

4 Análisis de resultados

En las Fig. 1 a 4 se observa cómo varían el beneficio total, las horas en DP, EQ, DP y la mezcla, en función del modelo utilizado:

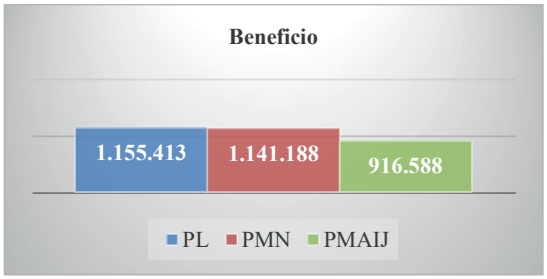

Fig. 1. Beneficio Total según modelo.

Este resultado indica que la mezcla de AIJ es la que arroja menor beneficio

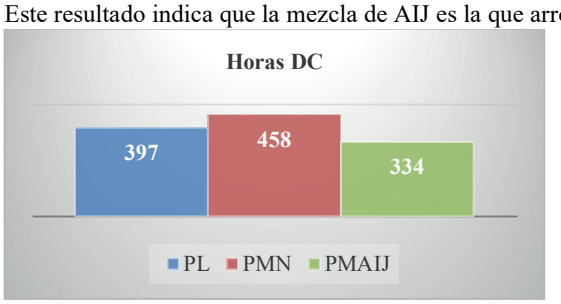

Fig. 2. Horas ocupadas en operación DC, Según modelo.

La PMN es la que más se acerca a la meta de máxima ocupación en DC

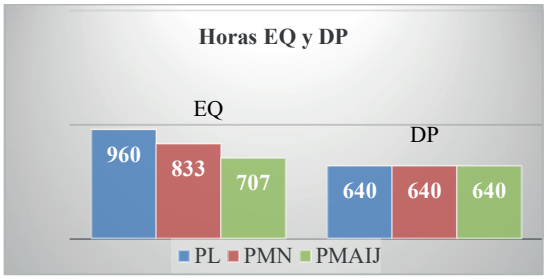

Fig. 3. Horas ocupadas en operaciones EQ y DP, según modelo.

Las horas ocupadas en DC, tanto de PMN como en PMAIJ son menores que las que arroja el modelo de PL.
Las horas ocupadas en DP no se ven afectadas por el modelo utilizado.

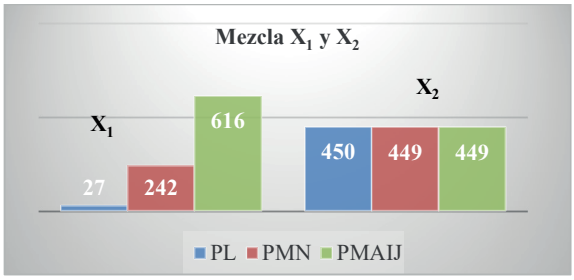

Fig. 4. Valor de mezcla para X_1 y X_2, según modelo.

Se observa que el valor de X_1 si bien no llega a la meta de 800, en PMN aumenta su valor respecto de PL y en PMAIJ alcanza el máximo valor alcanzado.

Respecto de X_2, se observa que la mezcla de PL es la que alcanza en forma rigurosa la meta buscada, aunque los modelos PMN y PMAIJ, prácticamente también lo hacen.

A modo de resumen de resultados, y considerando las metas planteadas, se puede afirmar que:

- El modelo de PL proporciona la mezcla que maximiza el beneficio;
- El efecto de considerar las metas igualmente ponderadas y normalizadas se observa que genera, un aumento de la utilización de horas de DC
- La máxima ocupación de EQ se obtiene para el modelo PL
- Las horas de ocupación de DP no se ven afectadas por la introducción de las metas en el modelo
- Finalmente, las mezcla que más ajusta a la meta 4 es el modelo de PMAIJ, que proporciona un 77% de la producción de X_1 y un 99,8% de la demanda de X_2, que es el mayor porcentaje alcanzado. Esta propuesta permite tomar la decisión de seleccionar el modelo de PMAIJ para la planificación de la producción.

Si bien es el modelo de menor rentabilidad, la metodología utilizada hace que esta decisión esté firmemente sustentada y en consecuencia de difícil objeción.

5 Conclusiones

El problema de obtención de la mezcla de producción en un entorno de múltiples cuellos de botella, se resuelve habitualmente utilizando la técnica de Programación Lineal.

No obstante, el empleo de este modelo, considera como único objetivo a tener en cuenta el beneficio.

La Programación por Metas en cambio, permite la consideración de otros objetivos que las partes interesadas puede suponer importantes en la determinación de la mezcla, confiriendo flexibilidad al modelo.

La Programación por Metas Ponderadas, además permite al decisor introducir su opinión respecto de la importancia de dichos factores. Dicha ponderación se puede realizar utilizando el Proceso Analítico de Jerarquías, de forma tal de no incurrir en inconsistencias al momento de emitir los juicios. El modelo AIJ permite incluir la opinión de todos los involucrados en la decisión.

La metodología propuesta de utilizar en forma conjunta el PAJ y la PMP en la determinación de la mezcla de producción en un entorno de múltiples objetivos resultó efectiva y de fácil aplicación, brindando resultados sólidamente sustentados.

Abstract. In this work, we introduce the order scheduling problem, in which customer orders (composed of different individual tasks) are scheduled, where the objective function is the minimization of the total tardiness of completed orders. In the reviewed literature, less studies regarding the problem of sequencing of customer orders were found compared with other production environments, such as, parallel machines or flow shop. In this work, we present a new variant for that problem, where we explicitly consider the setup times of machines dependent on the production sequence, which belongs to the NP-hard class. Then, we propose a new formulation using linear integer programming, an adaptation of the OMDD heuristic (referred to as OMMD-S), and a matheuristic called Same Permutation in All Machines (SPAM). The extensive computational simulations carried out show that the SPAM matheuristic is the most efficient for the evaluated instances.

Keywords: Production Sequencing. Heuristic. Matheuristic. Combinatorial Optimization. Mixed-Integer Linear Programming.

1 Introduction

A set of n orders needs to be processed on a set of m dedicated parallel machines, where each machine can process only one type of operation. Each order has an associated setup time, which is sequence-dependent, as well as a due date, related to the customer requirements. The customer order scheduling problem has several industrial applications, such as the paper industry, the pharmaceutical industry, and assembly operations [16]. Thereby, this production environment has received a lot of attention from many researchers [4].

Here, we present the literature review taking into account the notation provided by Framinan et al. [4]. Wagneur and Sriskandarajar [17] approached an open shop scheduling environment where the overlap of jobs in the available machines is allowed. The NP-hardness of the variant, taking into account the total tardiness minimization ($DPm \rightarrow 0||\Sigma T$), has been proven. Leung et al. [9] presented a notation for order scheduling linear programming models, considering several conditions for a given production environment and several objective functions. Roemer [16] approached the concurrent open shop where the jobs are processed in dedicated parallel machines. Contrary

to the statement presented by Wagneur and Sriskandarajar [17], Roemer re-established that, even for two machines, the problem for average completion time is NP-hard in the strong sense.

Leung et al. [10] approach the customer order scheduling problems that may present release dates and due dates. The class of objective functions treated involves total completion time and total tardiness performance measures, and the weighted total completion time objective is focused. The above-mentioned authors presented several structural properties and complexity analyses. Besides, two constructive heuristics, as well as a tabu search metaheuristic, are proposed.

Framinan and Perez-Gonzalez [2] addressed the customer order scheduling for total completion time minimization. A constructive algorithm with a look-ahead mechanism was proposed, which was used as an initial solution for a Greedy Search Algorithm (GSA) metaheuristic. Riahi et al. [15] developed eight dispatch rules, and a constructive algorithm, that considered all possible positions in the partial sequence for unscheduled orders. This constructive heuristic is used in a Perturbative Search Algorithm (PSA) metaheuristic.

Leung et al. [11] considered customer order scheduling problems with due date related objectives. Several performance measures are approached, and two objectives were focused: the minimization of the maximum lateness, and the total number of late orders. As solution procedures, a constructive heuristic and an exact algorithm were proposed. Lee [8] addressed the $DPm \rightarrow 0||\Sigma T$, and proven that the optimal solution for the total tardiness minimization is composed by the same permutation in all machines. Also, a mixed-integer linear programming formulation is presented. Finally, four constructive heuristics, as well as a Branch-and-Bound (B&B) algorithm, are proposed. In this study, OMDD heuristic may be considered as the best approximate algorithm for the problem. Framinan and Perez-Gonzalez [3] extended the constructive heuristic previously proposed for the total completion time objective [2] and developed two matheuristics called JPF and JPO. The second one is the state-of-the-art algorithm for $DPm \rightarrow 0||\Sigma T$ variant.

Kung et al. [7] addressed a customer order scheduling environment with unequal order ready times for the total completion time minimization. Two lower bounds are developed, and some problem properties were explored. Eight metaheuristics were proposed to solve the problem: four simulated annealings (SA) algorithms, and four genetic algorithms (GAs). Also, a Branch-and-Bound (B&B) algorithm was presented. Computational results point out that SA-based algorithms outperformed the GAs. Lin et al. [12] addressed a customer order scheduling environment with release dates for the minimization of the weighted number of tardy orders. Some dominance properties were explored, and a lower bound was presented. Besides, a B&B algorithm is developed to determine global optimal solutions. As solution procedures, these authors presented four standard bee colony algorithms, followed by four hybrid bee colony algorithms for finding near-optimal solutions within acceptable computational times. Wu et al. [18] introduced a customer order scheduling variant with ready times. Several dominance rules were explored, and two lower bounds were developed. These elements were considered in the developed B&B algorithm. These authors adapted five existing

constructive heuristics to the problem under study and proposed an Iterated Greedy (IG) metaheuristic.

Prata et al. [14] introduced the order scheduling problem with sequence-dependent setup times. Two mixed-integer linear programming models are proposed for this variant. Besides, two matheuristics are developed, which reduce the number of decision variables. The proposed Fixed Variable List Algorithm (FVLA) outperforms all other approaches.

Based on the literature review, we can observe that the variant introduced here is not reported previously. In a recent literature survey, Framinan et al. [4] have not reported contributions to the customer order scheduling environment with explicit setup times. In this paper, we introduce the customer order scheduling problem with sequence-dependent setup times for the total tardiness minimization. We present a mixed-integer linear programming model, as well as explore some problem properties. As a solution procedure, we extend two existing constructive heuristics. Also, we present a matheuristic procedure based on the reduction of the number of decision variables. Finally, we carried out extensive computational experiments with random-generated test instances.

The rest of this paper is organized as follows. In Section 2, we describe the problem under study. In Section 3, we present the proposed solution approaches. In Section 4, we summarize the computational results. Finally, in Section 5, we present the final remarks as well as suggestions for future works.

2 Problem description

2.1 NP-hardness of the proposed variant

Wagneur and Sriskandarajah [17] proven the NP-hardness of the problem $DPm \rightarrow 0||\sum T_j$. In the problem under study ($DPm \rightarrow 0|ST_{SD}|\sum T_j$), we consider explicitally sequence-dependent setup times for each customer order. Thereby, the problem under study is also NP-hard since it can be reduced to the $DPm \rightarrow 0||\sum T_j$ if $S_{ikl} = 0, \forall i,k,l$.

2.2 Proposed MILP formulation

Since the proposed variant is NP-hard, there is no exact algorithm to solve the problem within polynomial time. Thereby, a mixed-integer linear programming formulation can obtain near-optimal solutions or even global optimal solutions to the problem under study. Let n be the number of orders to be produced in a set of m dedicated parallel machines. Each order k has an associated due date d_k, a processing time p_{ik} in machine i, and a sequence-dependent S_{ilk}. The problem is to find a sequence of orders where the total tardiness is minimized. Next, we define the tardiness for a given order, as well as the total tardiness minimization.

The completion time in machine i for a given order processed in postion j of sequence Π, $C_{i,\pi_j}(\Pi)$, can be calculated recursivelly as in Equation (1):

$$C_{i,\pi_j}(\Pi) = C_{i,\pi_{j-1}}(\Pi) + p_{i,\pi_j} + S_{i,\pi_{j-1},\pi_j}, \quad i = 1,\ldots,m, \quad j = 1,\ldots,n, \qquad (1)$$

with $C_{i,\pi_0}(\Pi) := 0$, $\forall i$. Therefore, $C_{\pi_j}(\Pi)$ the completion time scheduled in position j is defined as in Equation (2):

$$C_{\pi_j}(\Pi) = \max_{1 \leq i \leq m} \{C_{i,\pi_j}(\Pi)\}. \tag{2}$$

Analogously, the tardiness of order scheduled in position j can be defined as in Equation (3):

$$T_{\pi_j}(\Pi) = \max\{C_{\pi_j}(\Pi) - d_{\pi_j}; 0\}. \tag{3}$$

Finally, the total tardiness is calculated as $T(\Pi) = \sum_{j=1}^{n} T_{\pi_j}(\Pi)$.

Likewise, the summation of the completion times $C(\Pi)$ for a given sequence Π can be calculated as $C(\Pi) = \sum_{j=1}^{n} C_{\pi_j}(\Pi)$.

We extend the MILP model presented by Framinan and Perez-Gonzalez [3], taking into account different permutations in the available machines. The problem notation is presented as follows.

Indices and sets

Set of machines $I = \{1, \ldots, m\}$;
Set of orders $K = \{1, \ldots, n\}$;
Set of positions $J = \{1, \ldots, n\}$.

Parameters

p_{ik} : processing time of the order k in machine i;
S_{ijk} : setup time of the order k in position j of machine i.
d_k : due date of the order k;
M : a sufficiently large number.

Decision variables

T_k : tardiness of order k;
C_{ij} : completion time of position j in machine i;
D_{ij}: setup time of position j in machine i.

$$x_{ijk} = \begin{cases} 1, & \text{if the order } k \text{ is processed in the position } j \text{ of machine } i. \\ 0, & \text{otherwise} \end{cases}$$

The MILP model is presented as follows:

$$\min \sum_{k=1}^{n} T_k \tag{4}$$

$$\text{subject to:} \quad \sum_{k=1}^{n} x_{ijk} = 1, \quad \forall i \in I, \quad \forall j \in J \tag{5}$$

$$\sum_{j=1}^{n} x_{ijk} = 1, \quad \forall i \in I, \quad \forall k \in K \tag{6}$$

$$S_{ijk}(x_{ij-1k} + x_{ijl} - 1) \leq D_{ij}, \quad \forall i \in I, \quad \forall j > 1, \quad \forall k,l \in K \tag{7}$$

$$\sum_{r=1}^{j} D_{ir} + \sum_{k=1}^{n} \sum_{r=1}^{j} p_{ik} \cdot x_{irk} \leq C_{ij}, \quad \forall i \in I, \quad \forall j \in J \tag{8}$$

$$C_{ij} - d_k + x_{ijk} \cdot M \leq M + T_k \quad \forall i \in I, \forall j \in J, \forall k \in K \tag{9}$$

$$x_{ijk} \in \{0,1\}, \quad T_k \geq 0, \quad C_{ij} \geq 0, \quad D_{ij} \geq 0, \quad \forall i \in I, \quad \forall k \in K, \quad \forall j \in J \tag{10}$$

The objective function (4) is the total tardiness minimization. Constraints (5) ensure that an order is scheduled only in one position of machine i. Set of constraints (6) enforces that a position is occupied only by a job from the order k in machine i. Set of constraints (7) calculates de setup time of the machine i in position j. We assume that all the machines are prepared in the first postion (the setups times are only computed if j is greater than 1). Set of constraints (8) computes the completion times of the orders. Constraint set (9) determines the tardiness associated with each customer order. Finally, constraint sets (10) establish the domain of the decision variables.

We define the M value as the summation of the processing and setup times, as in Equation (11):

$$M = \sum_{i=1}^{m} \sum_{k=1}^{n} p_{ik} + \sum_{i=1}^{m} \sum_{k=1}^{n} \sum_{l=1}^{n} S_{ikl} \tag{11}$$

Finally, it should be noticed that for this problem we have to consider the possibility of different permutations for every machine. Contrary to the variant without sequence-dependent setup times, where the optimal solution is obtained applying the same permutation on all the available machines [8]. Here, we show a counter-example to this fact.

Taking into account the following example, as described in Table 1. Also, we consider a due date of 5 time units for both orders.

Using the same permutation in all machines, we obtain the results illustrated in Figure 1, which present a total tardiness of the 4 and 8 time units, respectivelly. If we use distinct permutations in the machines, we can obtain a total tardiness of 3 time units, as illustrated in Figure 2. Thus, solutions with distinct permutations in the machines can lead to smaller total tardiness than solutions with fixed permutations in the machines.

Processing times		
	O_1	O_2
M_1	2	1
M_2	3	4

Setup times - machine 1		
	O_1	O_2
O_1	-	1
O_2	10	-

Setup times - machine 2		
	O_1	O_2
O_1	-	2
O_2	1	-

Table 1. Illustrative example.

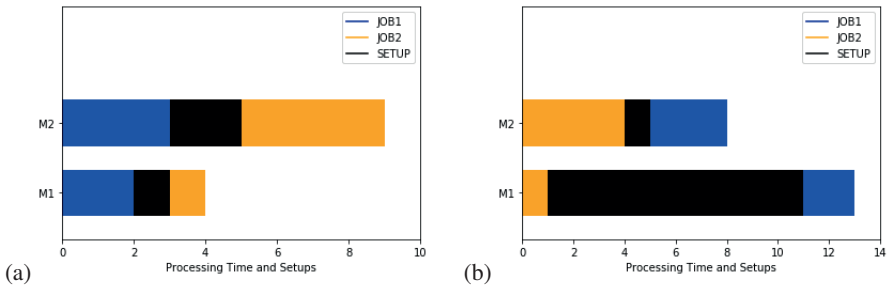

Fig. 1. Solutions with fixed permutations.

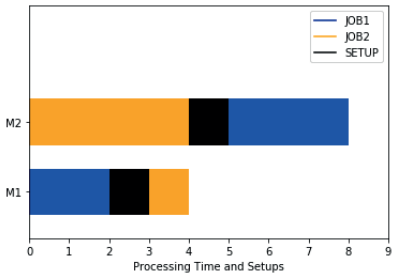

Fig. 2. Solution with distinct permutations.

3 Proposed solution approaches

Since the proposed variant is a NP-hard problem, we presented heuristic algorithms to find high-quality solutions within admissible computational time.

3.1 Constructive heuristics

The OMDD-S heuristic is an extension of the OMDD proposed by Lee [8], taking into consideration the sequence-dependent setup times. Our proposal is described in the following steps.

- Step 0: Set $\Omega := (1,2,\ldots,n)$ (unscheduled orders), $\Pi := \emptyset$ (scheduled orders) and $t_i = 0\ (1 \leq i \leq m)$.
- Step 1: Select order r in Ω with the minimum value of index α_j:

$$\alpha_j = \max\left\{\max_{1\leq i\leq m}\{t_i + S_{irj} + p_{ij}\} - \max_{1\leq i\leq m}\{t_i\}; d_j - \max_{1\leq i\leq m}\{t_i\}\right\}. \qquad (12)$$

- Step 2: Remove order r from Ω, append it at the end of Π.
- Step 3: Update t_i. If $|\Omega| = n-1$, then $t_i := t_i + p_{ir}$; otherwise, $t_i := t_i + S_{iwr} + p_{ir}$, where w is the last but one elemetn from Π.
- Step 4: While Ω is not empty, return to Step 1.

Also, we present the FP-S heuristic, as an extension of the FP algorithm proposed by Framinan and Perez-Gonzalez [3], taking into account the sequence-dependent setup times. The above-mentioned algorithm builds a solution $\Pi := (\pi_1, \ldots, \pi_n)$ from a set of unscheduled orders $\mathscr{U}$. Initially, $\mathscr{U}$ has all the orders, since none of the orders was scheduled. In iteration $\mathscr{K}$, each order in $\mathscr{U}$ is selected as a candidate to be inserted in the last position of Π. Aiming to select a given order from the candidate list, for each order $\omega_l \in \mathscr{U}$ with a due date d_l, a partial sequence S_l is builded inserting ω_l in the last position of Π, i.e. $\Pi := (\pi_1, \ldots, \pi_{k-1}, \omega_l)$.

Therefore, the tardiness indicator η_l for the candidate l is calculated as in Equation (13):

$$\eta_l = \max\{C(S_l) - d_l; 0\} + T^*(S_l) \tag{13}$$

where the first term is the contribution to the total tardiness if ω_l is selected, in which $C(S_l)$ is the completion time of the partial sequence S_l and d_l is the associated due date. The second term $T^*(S_l)$ estimates the contribution to the total tardiness of the remainder unscheduled orders. Figure 3.1 illustrates the FP-S constructive heuristic.

We adopt Ω as a given sequence where all the orders are included before the iterative procedure. For each iteration, we calculate $T^*(S_l)$ considering the remaining orders are scheduled after the orders in Π. We consider the sequence returned by the Earliest Due Date (EDD) heuristic. This algorithm is a well-known priority rule to solve a scheduling problem with due dates [13]. We select a given order, append it at the end of the partial sequence, and remove it from Ω. As the remaining orders in Ω are already sorted, they are not calculated again in the next iteration.

3.2 Matheuristic

An intuitive procedure to solve the problem under study is to consider a fixed permutation in all machines. In this way, we can replace the decision variable x_{ijk} in the model defined in Equations (4) - (10) by a decision variable x_{kj} equals to 1 if the order k is processed in position j, 0 otherwise. This matheuristic called Same Permutation in All Machines (SPAM) reduces the number of binary decision variables from mn^2 to n^2. We can observe that the optimal solution returned by the SPAM matheuristic not necessarily is the optimal solution to the original problem.

4 Computational results

4.1 Experimental design

Since the problem under study was not reported yet, we randomly generated the evaluated test instances, based on the related instances previously presented [8,3]. The

Algoritmo: FP-S

Input : Number of machines m, number of orders n, processing time p, due dates d, setup times s.
Output : Permutation Π
$\Pi := \emptyset$;
Obtain sequence $\Omega := (\omega_l, \ldots, \omega_n)$ by sorting orders according to EDD rule;
Set $ct_i = 0$ $(1 \leq i \leq m)$;
//Append orders one by one
for $j = 1$ *to* n **do**
  //Compute indicator for each unscheduled order
  for each $\omega_l \in \Omega$ **do**
    //Compute ect_i the estimated completion times of ω_l for each machine i;
    for $i = 1$ *to* m **do**
      $ect_i = ct_i + p_{iw_l} + s_{ilw_k}$
    end
    Where l is the last element of Π
    //Compute first term of indicator η_l, see Equation 13
    $\eta_l = \max\{\max_{1 \leq i \leq m}\{ect_i\} - d_{w_l}; 0\}$
    //Compute second term of indicator η_l
    for each $w_k \in \Omega - \{w_t\}$ **do**
      for $i = 1$ *to* m **do**
        $ect_i = ect_i + p_{iw_k} + s_{ilw_k}$
      end
      $\eta_l = \eta_l + \max\{\max_{1 \leq i \leq m}\{ect_i\} - d_{w_k}; 0\}$
    end
  end
  //Select order with minimum value of η_l
  $r := argmin_{1 \leq l \leq n-j+1} \eta_l$
  Append ω_l at the end Π, i.e. $\Pi := (\pi_1, \ldots, \pi_{j-1}, \omega_r)$
  Extract ω_r from Ω, i.e. $\Omega := (\omega_l, \ldots, \omega_{r-1}, \omega_{r+1}, \ldots, \omega_{n-j+1})$
  //Update completion times
  for $i = 1$ *to* m **do**
    $ct_i = ct_i + p_{iw_r} + s_{ilw_r}$
  end
end

Fig. 3. Pseudocode of FP-S constructive heuristic.

testbed is composed of test instances with $n \in \{10, 20, 30, 40\}$ and $m \in \{2, 5, 8\}$. The processing times follow an uniform distribution $U[1, 100]$. The sequence-dependent setup times follow three uniform distributions $\{U[1, 25], U[26, 75], U[76, 125]\}$. The due date d_k follows a uniform distribution $U[P(1 - TF - RDD/2), P(1 - TF + RDD/2)]$, where:

– P is the sum of processing and setup times divided by the number of machines. Aiming to generate tight due dates, we multiply this expression by a factor μ.

$$P = \left\lceil \frac{\sum_{i=1}^{m}\sum_{k=1}^{n} p_{ik} + \sum_{i=1}^{m}\sum_{k=1}^{n}\sum_{l=1}^{n} S_{ikl}}{m} \right\rceil \cdot \mu,$$

- *RDD* is the interval for due dates: $RDD : \{0.2, 0.5, 0.8\}$;
- *TF* is the tardiness factor for the due dates: $TF : \{0.2, 0.5, 0.8\}$

For each combination of parameters were generated 10 test instances, totalizing 3240 instances. The methods under comparison are listed below.

- EDD heuristic. ;
- OMDD heuristic [8];
- FP heuristic [3];
- The proposed OMDD-S heuristic;
- The proposed FP-S heuristic;
- The proposed SPAM matheuristic;
- The proposed MILP model.

We used the Relative Deviation Index (*RDI*) indicator as a performance measure, which is a standard indicator for scheduling problems with due-date objectives [6,1,5]. Let H be a set of methods, the *RDI* obtained for the method $s \in H$ when applied to instance t is calculated as in Equation (14).

$$RDI_{st} = \begin{cases} 0, \text{ if } \min_{h\in H} T_{ht} = \max_{h\in H} T_{ht}, \\ \frac{T_{st} - \min_{h\in H} T_{ht}}{\max_{h\in H} T_{ht} - \min_{h\in H} T_{ht}} \cdot 100, \quad \text{otherwise.} \end{cases} \tag{14}$$

where T_{st} is the tardiness value obtained by heuristic s in instance t. In our case $\min_{h\in H} T_{ht}$ is the optimal value if the MILP model is able to find the optimal solution within the assigned computation time, or the best solution found among the heuristics and matheuristics otherwise. The methods under comparison were implemented with Python 3.7. Furthermore, the MILP model and the SPAM matheuristic were solved with IBM ILOG CPLEX version 12.8.0. For all methods under comparison, we adopt a time limit t_{limit} = 600s. All the algorithms were run in an Intel Core i5-3470 with 3.20 GHz and 8 GB RAM.

4.2 Results and discussion

Table 2 illustrates the computational results for different values of m and n. Taking into consideration the first set of instances ($m = 2$ and $n = 10$), we can observe that the MILP model returns the best solutions among all the considered methods. However, with the increasing of the values of m and n, OMDD-S and SPAM return the best *RDI* values.

Based on Table 2, we can observe that FP-S algorithm outperforms the FP heuristics since the first one presents smaller average *RDI* values for all the sets of instances, except for the problems with $m = 8$ and $n = 40$. However, the difference between the

RDI values between FP-S and FP heuristics in these test instances is only 0.0363%. We can also emphisize that OMDD-S algorithm outperforms the OMDD heuristic since it returned best average *RDI* values for all the test instances. Furthermore, OMDD-S presented the better results taking into account all the methods under comparison for the test instances with $m = 2$ and $n = 40$, $m = 5$ and $n = 30$, $m = 5$ and $n = 40$, $m = 8$ and $n = 30$, and $m = 8$ and $n = 40$.

Table 2. *RDI* values for m and n.

Table 3 presents the *RDI* values (average and standard deviation) taking into account *TF* and *RDD*. Once again, SPAM and OMDD-S have returned the best values for the RDI indicator. Also, the FP heuristic has presented the worst performance among the methods under comparison.

Taking into consideration the Table 3, we can observe that FP-S algorithm outperforms the FP heuristic for all the evaluated test instances. In addition, the OMDD-S algorithm outperforms the OMMD heuristics also for all the test instances. Finally, we can highlight that the SPAM matheuristic presented better average *RDI* values than the MILP model for all the available test instances.

Table 3. *RDI* values for TF and *RDD*.

Figure 4 illustrates the boxplot for average *RDI* values taking into consideration the parameter TF. Based on achieved results, we can observe that SPAM matheuristic returned the best results for all the values of TF. Besides, the MILP model presented the worse results for TF equals to 0.8. Figure 5 illustrates the average *RDI* values depend-

ing on *RDD*. Once again, the SPAM matheuritic outperformed all the other methods under comparison.

5 Conclusions

In this paper, a new variant for the customer order scheduling problem has been investigated, taking into consideration explicitly sequence-dependent setup times. The objective function is the total tardiness minimization. A mixed-integer linear programming formulation has been proposed for the problem under study. Furthermore, two constructive heuristics as well as a matheuristic based on the decision variable fixations have also been presented. The proposed matheuristic is a promising method to solve the problem under study since it outperformed all the other methods under comparison.

As extensions of this work, other matheuristics and matheuristics could be developed to improve the solutions found. The OMDD-S heuristic could be used as a warm start to MILP and SPAM methods, improving the solutions returned by these methods. Another possibility is the consideration of different objective functions for the proposed variant, such as total completion time.

A Research Direction in Manufacturing Systems Scheduling: A proposal*

Fantahun Defersha

School of Engineering, University of Guelph, 50 Stone Road East, Guelph, Ontario, Canada, N1G 2W1

Abstract. Manufacturing is the most important wealth-generating sector of a developed nation. However, this very important economic sector is facing intense global competitions. To be successful in this competitive climate, manufacturers require significantly improved capabilities. Technology, in the form of equipment and automation, has always been a means to competitiveness. However, an equally important and a determining avenue to competitiveness is the way we organize facilities, plan production and schedule operations. Production planning and scheduling has become a necessity for survival and its importance cannot be overstated. It is a critical decision making process of allocating limited resources to tasks over time, while many time and relationship constraints among the activities and resources are being satisfied. Indeed, it ultimately determines the operational performance of a manufacturing system. It is also one of the very difficult optimization problems known to the research community and has been an active field of research for many decades. Countless number of articles are published in the area. However, very little has been written on how to bring theoretical research into practice. Perhaps the research community has over emphasized the mathematical rigor at the cost of under-emphasizing real implementations. In this article, we discuss how to make scheduling research relevant in a form of new research directions.

Keywords: Manufacturing Systems Scheduling; Empirical Study; Meta-Scheduling; Dynamic Scheduling; Supervisory Control.

1 Introduction

Production scheduling has become a necessity for the survival of manufacturing firms in today's competitive marketplace (Kostas et al., 2003). It is a critical decision making process of allocating limited resources to tasks over time in or-der to produce the desired outputs at the desired time. Indeed, it ultimately determines the operational performance of a manufacturing system (Wiers and Tjerk W. Van Der Schaaf, 1997). Production scheduling usually involves a very

* Corresponding Author: F. Defersha, Email: fdefersh@uoguelph.ca, Home Page: www.defersha.ca

large number of variables and constraints and it is one of the very difficult combinatorial optimization problems known to the research community. To this end, it becomes an active field in operations research and countless number of arti-cles are published in the area. However, most published articles are focused in developing models and algorithms for theoretical scheduling problems having well-defined structures such as job shop, flow shop, parallel machine shop and their variants. Whereas, scheduling in practice, varies greatly between different companies with no definitive model of "real world" scheduling available to aid manufacturing industries. Very little has been written on how to bring theoretical research into practice. This has given rise to the so-called "gap" between theory and practice of scheduling (MacCarthy and Liu, 1993). For instance, in a quantitative study about scheduling research carried out by Reisman and Kumar (1997), from a total of 184 reviewed papers, only 5 (less than a 3%) dealt with realistic production settings. Indeed, several other studies on production planning and scheduling have also concluded that there exists a gap between theory and practice (e.g. McKay and Wiers (1999), Wiers and Tjerk W. Van Der Schaaf (1997), Portougal and Robb (2000), Kostas et al. (2001), Gupta (2002), Mon-tana (2002), Méndez et al. (2006), Proth (2007), Framinan and Ruiz (2010), Jahangirian et al. (2010), De Snoo et al. (2011), Frantzén and Moore (2011), Framinan and Ruiz (2012), Carvalho et al. (2014)).

Sample statements in literature about the apparently perceived gap between theory and practice in scheduling are listed below:

- The academic literature presents a lack of studies examining the implementation of production scheduling solutions in real contexts (Carvalho et al., 2014).
- Advances in scheduling theory have had only a limited impact in practice (Pinedo, 2008).
- Research in scheduling has been motivated by what the researchers can achieve rather than what is important and suffers from much abstractions and too little application (Gupta and Edward, 2006).
- While advances in scheduling theory had become broader and covered more areas, industrial executives felt that the realistic scheduling problems were not being solved (Gupta, 2002).
- A big proportion of the theoretical research in scheduling done during the decades past is of limited use in real-world applications (Kostas et al., 2001).
- A proliferation of scheduling research has done little to improve production planning practice, despite calls for more comprehensive model (Portougal and Robb, 2000).
- Production scheduling in industrial practice is still primarily a manual task, despite immense research efforts and the fact that manual scheduling is a very complex task (Wiers and Tjerk W. Van Der Schaaf, 1997).

From the above review and other literature, it is apparent that there is consensus in the research community that theoretical research in developing algorithms for scheduling has done little to improve the scheduling practice. Perhaps the operations research community has over-emphasized the rigor in

mathematical treatment at the cost of under-emphasizing real implementations. Most scheduling tasks that could potentially benefit from automated scheduling are performed manually, that produces highly suboptimal schedules (Montana, 2002). The majority, if not all, of the contemporary enterprise resource planning (ERP) software do not support the production scheduling function (Kostas et al., 2003). In addition to those literature assertions, after conducting scheduling research in the past seven years and having seen several real life industrial problems, the author strongly believes that the countless scheduling algorithms appeared in literature have very limited use in practical settings. Thus, a scheduling research that better address the needs of the real world manufacturing industries is of a paramount importance which is the main driving force of the research proposal presented in this paper.

2 Proposal for Research Directions

2.1 Empirical Study

Real-world scheduling problems are extremely different from conventional research problems and quite often they are very complicated. One problem encountered by the author of this article in a local industry (with no resemblance to any scheduling problem in literature) involves a highly paced upstream continues process of a constant speed feeding hundreds of intermittent downstream operations interconnected by a network of conveyors. The scheduling of the downstream operations calls for a balance of material flows at each processing station and meeting production demands within posted time-windows. Another real-life scheduling problem, yet totally different from theoretical problem, encountered by the author involves the scheduling of parallel workstations feeding many different parts to a loop conveyor. Part carriers for different products are mounted on the conveyor on which parts are further processed. The carriers/fixtures for the different products have be added or removed from the conveyor to meet production schedules. The loading/unloading and the sequencing of the part-carriers on the conveyor and the operation of the parallel stations have to be synchronized to avoid starvation or congestion of the system and at the same time meet very tight production schedule. The above two encounters are just the tip of the iceberg. Industries are full of scheduling problems that are quite different from theoretical problems. Thus, for realistic problem formulations, an in-depth empirical study on the practice of manufacturing scheduling is much needed. In conducting empirical studies, researchers are advised to closely examine real life problems in industries and conduct extensive surveys. Using the results of such empirical study, it can be possible to develop generalized frameworks and guidelines for manufacturing systems scheduling that are usable in wide variety of practical scenarios.

2.2 Meta-Scheduling Procedure

A major problem in translating scheduling algorithms to real systems is that most algorithms are framework specific such as job-shop or flow-shop which

rarely match real systems Plenert and Kirchmier (2001), Mejía et al. (2012). In this research direction, researches are encouraged to develop a generalized framework and algorithm (meta-scheduling) that can be used to schedule a wide range of discrete manufacturing systems without altering its internal code. The manufacturing systems that can be scheduled with such algorithm can be a single machine shop, parallel machines shop, flexible flow shop, flexible job shop, cellular, virtual cellular, distributed, or hybrids of these layouts. Based on this framework, a meta-data structure, a meta-model and efficient solution procedure can be developed that can solve many of the discrete manufacturing systems scheduling problems appeared in literature. Such system independent generalized meta-scheduling algorithm can be more usable in practical settings as it will enable manufacturing system scheduler use the same scheduling tool in a variety of scenarios. This will also enable ERP tool developers to incorporate scheduling function as the algorithm can be coded without a specific system in mind and can handle a variety of scenarios without changing its coding.

2.3 Scheduling with Multiple Performance Metrics

The vast majority of scheduling algorithms in literature consider a single objective function (usually makespan). Whereas, the multi-objective ones added only one or two from the very limited list of other performance metrics such as earliness, lateness and tardiness that are well stabilised in scheduling research. Other performance measures, such as work-in-process inventory, machine utilization, and work-load balancing are not usually considered in scheduling while these performance metrics are ultimately impacted by scheduling. To address this issue, the meta-scheduling framework, highlighted in the previous section, has to be designed to be flexible enough to handle multiple objective functions and a variety of operational logics and constraints in manufacturing systems.

2.4 Integrated Dynamic Scheduling/Supervisory Control

Another major limitation of scheduling algorithms in literature is that most of them are designed assuming static conditions. However, manufacturing systems operate in dynamic environments where frequent real-time events occur making a previously feasible schedule obsolete. Examples of such real-time events include machine failures, arrival of urgent jobs, cancellation of orders, due date changes, operator absentee etc. To address this problem, algorithms need to be designed in such a way that they can be executed on (1) a fast simulated time to perform planning and scheduling, and (2) on a real time to perform supervisory control and automatic updates on the production schedule. In literature and in practice as well, supervisory control and scheduling are separate functions. Whereas, in this research direction, an integrated approach has to be pursued.

3 Suggested Methodology

The framework and the solution methodology to be develop is a hybrid approach combining metaheuristic algorithms (such as genetic algorithms) and Event-Scheduling/Time-Advance algorithm from the theory of discrete event systems simulation. This framework is depicted in Figure 1. The "Job Release Queue" is a set of alternative job dispatching sequences, to be iteratively improved and supplied by the metaheuristic algorithm. The schedule generator (the central part in Figure 1) works following the Time-Advance-Event-Scheduling algorithm as described in details in Figure 2. In that figure, a job in queue in front of a particular machine (resource) m is identified as (o, j, t_{ojm}) which represent operation o of job j and its future completion time t_{ojm}. The corresponding future job completion event is listed in a calendar as (o, j, m, t_{ojm}) in which all other job completion events are listed in chronological order. The schedule generator (running in a simulated time) provides schedules and performance measure for each potential job-release-sequence. Then, genetic operators are applied to provide a new set of job-release-sequences for the next iteration. The iteration continues until a predefined stopping criterion is met. The following paragraph briefly elaborates how this algorithm can be expanded to become a system independent multi-objective meta-scheduling tool by incorporating many pragmatic issues.

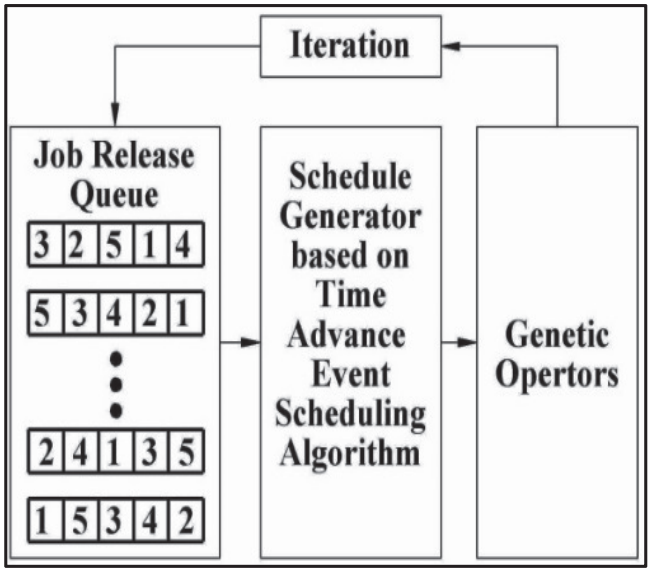

Fig. 1: The framework of the proposed methodology

As it can be seen in Figures 1 and 2, the algorithm does not require the type of machine layout adopted in the system as an input. Moreover, a resource m in the

schedule generator can be defined either as a unit processing (e.g. lathe, milling), a batch processing (e.g. heat treatment) or a continuous processing (e.g. painting line) or a material handling resource or even as buffer storage. As such, the algorithm can be expanded to handle a wide range of discreet and semi-discrete manufacturing systems with greater operational complexity. The schedule generator is based on Event-Scheduling/Time-Advance algorithm of discrete event systems simulation. Thus, in addition to time related performance measures (e.g. makespan), the schedule generator can be expanded to evaluate many performance measures such as work-in-process inventory, machine utilization, and workload balancing among others. These performance measures are ultimately affected by scheduling whereas traditionally scheduling models do not incorporate them. In generating a schedule, the schedule-generator is to be executed in a simulated time. Once an optimized schedule is in place, the schedule generator is to run in real time to become a supervisory controller and monitor the schedule and react for unexpected events. To achieve this, the proposed framework need to have database modules for integration with IT-infrastructure. The framework can also incorporate problem specific modelling capability, parallel computations and artificial intelligence (AI) for self-parameter tuning.

Initialize	• Get a Job-Release-Queue (JRQ) from the solution population (Left part of Fig. 1). • Set the current time $t_{current} = 0$
Step 1	• Is there is an Operation-Completion Event (o-j-m-t_{ojm}) at the top of the event list to occur at the current time (i.e. $t_{ojm} = t_{current}$)? If yes go to Step 2; Otherwise go to Step 3
Step 2	• Remove Event ($o - j - m - t_{ojm}$) from the top of the event list of the calendar. • Remove Operation ($o - j - t_{ojm}$) from the front of job queue of machine m. • If operation o of job j is not the last operation, assign operation $o + 1$ of this job to the alternative machine m' that can complete this operation at earliest time. Say the completion time is $t_{o+1,j,m'}$. • Append Operation ($[o + 1] - j - t_{o+1,jm'}$) at the tail of operations queue of machine m′ and insert Event ($[o + 1] - j - m - t_{o+1,jm'}$) in the calendar. Go to Step 1.
Step 3	• Are there machine(s) that are currently (at $t = t_{current}$) idle. If yes, go to Step 4. Otherwise Go to Step 7
Step 4	• If there is a job in the (JRQ), go to Step 5. Otherwise, go to Step 7.
Step 5	• Starting from the front the JRQ, look for a job whose first operation can be assigned to one of these idling machines. If there is such a job (j'), remove this job from JRQ and go to Step 6. Otherwise, go to Step 7
Step 6	• Among the idling machines that can process the first operation of job j', find the one that can finish this operation at the earliest time. Say this machine is machine m'' and the completion time is $t_{1,j',m''}$. Append operation ($1 - j' - t_{1,j'm''}$) to the empty queue of machine m''. Insert event ($1 - j' - m'' - t_{1,j'm''}$) in the calendar list. Go to Step 3
Step 7	• If the calendar list is not yet empty: advance the time to the time of the event at the top of the event list (say this event is $o - j - m - t_{ojm}$): $t_{current} = t_{ojm}$. Then, go to Step 2. Otherwise, go to Step 8
Step 8	• The JRQ is completed and the current time is the makespan ($Makespan = t_{current}$)
Next	• Start again from Initialize Step until all JRQ are evaluated.

4 Feasibility of the Proposed Methodology (A proof concept)

The research direction in Section 2.1 can be accomplished mainly through direct observation of real systems and surveys followed by critical analysis of the information gathered in order to develop new guidelines/frameworks for a generalized scheduling algorithm. As for the other research direction, the author conducted a preliminary study (as a proof of concept) to develop a unified meta-scheduling procedure based on the proposed framework for the job-shop and the flow shop problems described in Defersha and Chen (2010) and Defersha and Chen (2012), respectively. The generalized method was found to be comparable to (or better than) the specialized algorithms developed in those two articles. This clearly shows the feasibility of the methodology in achieving those objectives. Recently, the author has been also working in an industrial scheduling problem titled "Integrated Operations and Manpower Scheduling" in collaboration with a local industry. The manufacturing facility encompasses features from job-shop, flow-shop, unit processing, batch processing, assembly, among many others. The system is also very dynamic as it involves many small batch products with frequent changes in product mix and demand. The framework proposed in this research was followed to implement the concept of dynamic scheduling and supervisory control. The results demonstrate the feasibility of the methodology in pursuing the research direction in Sections 2.2, 2.3 and 2.4. Metaheuristics and time-advance-event-scheduling algorithm are individually proven to handle a wide range of problems in manufacturing systems analysis. This makes their combined use to be the most feasible choice in pursuing the proposed research directions.

5 Research Novelty and Anticipated Impacts

Though many researchers recognize the benefit of system independent scheduling tools, there are only few published attempts. Davis and Fox (1994) and McIlhagga (1997) both make initial attempts in developing a system independent scheduling frameworks, but fall short in terms of generality and flexibility of the frameworks they propose. Smith and Becker (1997) and Kostas et al. (2001) create unified scheduling ontologies, but the ontologies are not well suited for an easy problem representation and solution encoding and not suitable for optimization. A scheduling methodology that can be used across domains (job-shop, traveling sales man, vehicle routing) was patented by Montana and Herrero (2000) and presented in Montana (2001). However, the approach lacks depth in each domain and cannot address the challenges of today's complex manufacturing systems. Framinan and Ruiz (2010, 2012) provide guidelines and architecture for unified scheduling tools. However, the authors provide broad-brush approaches on the problem and lacks specific algorithm development. The research proposed in this article is unique and novel in developing a scheduling algorithm that is more flexible to be used in wider range of manufacturing systems. This will enable ERP

developers incorporate detail scheduling functionalities in their software and also enable industries acquire automated scheduling tool without the need to develop expensive customized algorithms. On top of its generality, the proposed method is unique by enabling the optimization of many performance measures that are highly influenced by scheduling but not addressed in scheduling literature. The proposal is also unique by unifying supervisory control and schedule into a single tool to address the dynamic/stochastic nature of manufacturing systems.

6 Concluding Remarks

Technology, in the form of equipment and automation, has always been a means to competitiveness. However, an equally important and a determining avenue to competitiveness is the way we organize facilities, plan production and schedule operations. Production planning and scheduling has become a necessity for survival and its importance cannot be overstated. It is a critical decision making process of allocating limited resources to tasks over time, while many time and relationship constraints among the activities and resources are being satisfied.

A scheduling problem usually involves a very large number of variables and constraints and it is one of the very difficult combinatorial optimization problems known to the research community. To this end, it becomes an active field in operations research and countless number of articles are published in the area. However, most published articles are focused in developing models and algorithms for theoretical scheduling problems having well-defined structures such as job shop, flow shop, parallel machine shop and their variants. Whereas, scheduling in practice, varies greatly between different companies with no definitive model of "real world" scheduling available to aid manufacturing industries. Thus, applied research endeavors and their publications are very timely and much needed in solving realistic scheduling problems in wide range of industries.

Abstract. In this paper, we study a particular case of a Group Shop Scheduling that we call Fixed Group Shop Scheduling (FGSS). In a FGSS, each job has the same number of stages, and the operations for the job than must be processed at the stage in the k-th position share the same set of machines with the other jobs. To solve the FGSS, we applied a modified Tabu Search heuristic. Our contribution consists in adapting the well-known Giffler and Thompson algorithm embedded with a self-tuning mechanism that guarantees semi-active schedules. An empirical study of different approaches including constraint programming and mixed-integer linear programming exhibited competitive performance of our proposed approach.

Keywords: Scheduling, Fixed Group Shop, Constraint Programing, Metaheuristics.

1 Introduction

In this paper, we address a special case of a Group Shop Scheduling Problem (GSS) that we call Fixed Group Shop Scheduling (FGSS). An example of a FGSS consists in a mechanical workshop were routine car maintenance operations must be performed. Naturally, the number of operations for each job (*car*) j and their processing times depends on different factors as the odometer count and the time between maintenance. Indeed, for each car j the set of maintenance operations can be divided into stages where it is necessary to complete all the operations on stage s in an arbitrary order (i.e. change the air filter, change the motor oil, etc.) to continue to the following stage $s + 1$ (i.e. car's washing and cleaning), and so on. In this context, it is desirable to minimize the flow time of each car in the workshop to meet the customer's expectatives. Also, some setup operations may be required between two consecutive cars. Hence, we considerer setup times between two consecutive operations at each machine. To the best of our knowledge, the FGSS has not been studied before and for these characteristics and practical applications, we consider that it deserves dedicated attention.

The paper is organized as follows: section 2 corresponds to the literature review. Section 3 presents the FGSS. Section 4 describes the modified Tabu Search (mTS) and computational experiments. Section 5 concludes and proposes future work.

2 Literature Review

The GSS problem was first introduced in [1]. A GSS consists of a set of m different machines that perform operations of n jobs, where each job j has s_j stages of operations. A stage s_j consists of a subset of operations of a job j that can be processed in any arbitrary relative order, while the stages of a job must be processed in a predetermined order $1,2,\dots,s_j$ [2]. Almost most papers for the GSS focus on finding a solution that minimizes the makespan ([2], [3], [4], [5], [6]). The consideration of sequence-dependent setup and transportation times have been proposed as extensions for the GSS [7]. Additionally, other publications consider stochastics and/or fuzzy extensions for the GSS ([3]). The main metaheuristics used to solve the GSS are Genetic Algorithm ([2], [7]), Tabu Search ([2], [5], [6]) and Ant Colony Optimization ([4]).

3 Fixed Group Shop Scheduling Problem

In a FGSS environment, each job has the same number of stages, and the operations for the job than must be processed at the stage in the k-th position share the same set of machines with the other jobs. In Table 1 we give an example for the total flow time FGSS. The processing times for Job 1 (J_1) are 1, 3, 4, 2 and 1 at Machines $M_1 \dots M_5$, respectively. Moreover, operations O_1, O_2 y O_3 for J_1 belong to the Stage 1 (S_1), thus could be processed in an arbitrary order. Then, after finishing their operations at S_1, J_1 continues its process at S_2 and finally completes its process at S_3.

Table 1. Processing times of a small-sized instance for the FGSS.

Stages	S_1	S_1	S_1	S_2	S_3
Jobs / Machines	M_1	M_2	M_3	M_4	M_5
Job 1	1	3	4	2	1
Job 2	2	1	3	1	4
Job 3	3	2	1	4	2

In Fig. 1 we show two solutions for the FGSS instance proposed in Table 1. The disjunctive graph presented in Fig. 1 (Left) represents an arbitrary solution with $\sum_j F_j = 41$, where the red dotted directed arcs show the sequence at the machines. Analogously, the black dotted directed arcs show the groups-permutations (i.e. the route of operations for J_1 at S_1 is O_1, O_3 and O_2, then must follow the route $M_1 - M_3 - M_2$). In Fig. 1 (Right) we show a disjunctive graph corresponding to an optimal solution with $\sum_j F_j = 38$. For both solutions, we provide a Gantt chart representation.

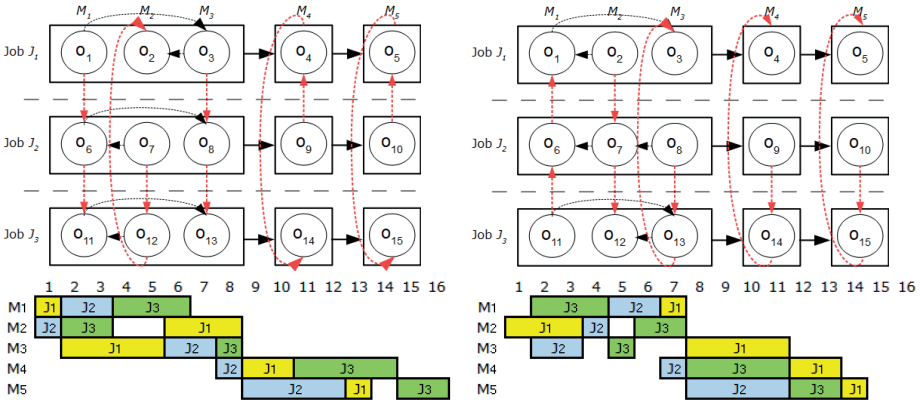

Fig. 1. (Left) An arbitrary feasible solution for the FGSS instance presented in Table 1 with $\sum_j F_j = 41$. (Right) An optimal solution for the FGSS instance presented in Table 1 with $\sum_j F_j = 38$.

4 Solution method

We propose a modified Tabu Search (mTS) that uses a permutation list representation. The eligible set of operations to be scheduled was chosen following the guidelines discussed in [8]. The well-known Giffler and Thompson (G&T) [9] appending algorithm in this context guarantees semi-active schedules. To avoid redundancy, we embedded in our mTS a mechanism that prevents a previously accepted schedule will be accepted again in a further iteration. To choose an operation to be scheduled from the eligible set we use the self-tuning approach proposed by [10]. All the experiments use as initial solution a permutation list provided by the Shortest Processing Time (SPT) dispatching rule. Finally, we use a swap as an operation movement. Preliminary computational experiments were tested on 40 instances from [10]. To adapt these instances to the FGSS, the operations of each job were assigned to a stage. Instances and detailed results could be consulted at: https://tinyurl.com/yxbwpq99.

4.1 Performance

The experiments were run on an Intel® Core™ i7-7500U CPU @ 2.70GHz processor with 16Gb RAM using the proposed mTS, MILP CPLEX 12.10, GUROBI 9.0.2, and the ILOG CPLEX ™ CP optimizer (12.10). The stopping criterion was a maximum running time established with the formula $jobs \times machines$ seconds. The performance measure was the Relative Percentage Deviation (RPD):

$$RPD = \frac{objective - bestObjective}{bestObjective} * 100\% \quad (1)$$

$objective$ is the value of the objective function of a given solution and $bestObjective$ was either the optimal value or the best-known solution (bks). The average (AVG) for the mST was obtained after running each instance 10 replicates with different seeds.

Table 2. RPD calculated over the randomly generated instances $FGSS_m/S_{jik}/\sum_j C_j$

Size	CP AUTO	CP DF	CP RS	CP MP	CP ID	CPLEX 12.10	GUROBI 9.0.2	mTS BEST	mTS AVG
4×4	**0.00%**	**0.00%**	**0.00%**	**0.00%**	**0.00%**	**0.00%**	**0.00%**	**0.00%**	**0.00%**
5×5	**0.00%**	1.56%	**0.00%**	0.24%	2.84%	**0.00%**	**0.00%**	**0.00%**	**0.00%**
7×7	1.38%	22.09%	1.03%	3.24%	5.72%	6.05%	7.63%	**0.00%**	0.97%
10×10	1.14%	36.23%	2.93%	3.80%	4.99%	10.95%	23.26%	0.25%	2.25%
Avg.	0.63%	14.97%	0.99%	1.82%	3.39%	4.25%	7.72%	**0.06%**	**0.81%**

For instances of 4x4 and 5x5, all the approaches reach the optimum. For instances of 7x7 and 10x10 the optimum could not be verified, thus the RPD was calculated over bks. In this case, the MILP approach was outperformed by both, CP and mTS. Finally, our mTS exhibited competitive performance in contrast with the CP approach.

5 Conclusions and future works

The preliminary computational results show consistency and competitiveness of our mTS to solve the total flow time FGSS with sequence-dependent setup times compared with CP and MILP. However, more computational experiments are needed with larger instances. As a future work, we consider exploring other schedule generation schemes that guarantee an active schedule in the presence of setup times.

Abstract. In this paper we address an extension of the economic lot-sizing problem with remanufacturing, in which environmental costs are considered in the objective function in addition to the traditional economic costs. Separate costs for emissions, water and energy consumptions are assumed for the manufacturing and remanufacturing activities as well as to carry on positive inventories of both used and serviceable products. We provide a mixed-integer linear programming formulation for the problem and suggest several solving procedures based on the Tabu Search metaheuristic. In order to evaluate the suggested procedures, we compare them against an optimization solver over a benchmark set of instances of the literature extended for the problem. From the results obtained of the numerical experimentation, we can conclude that the suggested procedures are able to achieve near optimal solutions in a time-effective way. This effect is particularly significant for large instances of the problem. In addition, we consider an objective function with weighted costs, in order to analyze the effect of including environmental costs in the hybrid production-remanufacturing systems.

Keywords: Lot-sizing problems, Remanufacturing, Environmental costs, Optimization, Heuristics, Tabu Search.

1 Introduction

Production planning is crucial for industrial companies [1]. The basic production problem involves to determine how much and when to produce of a certain product in order to fulfill the demand requirements on time, minimizing the sum of the involved costs of production and storage. This problem is commonly known in the literature as the Economic Lot Sizing Problem (ELSP) [2].

Manufacturing has an impact on the planet's ecology. The emissions coming from the processing and use of fossil fuels that reach the atmosphere and the industrial garbage impact all forms of life around the world, causing irreversible damage to the ecosystem. These are just some of the environmental problems caused by pollution from factories [1, 3].

Circular Economy is an alternative that promotes to change the traditional linear production model consisting on producing, using and discarding, for one where used products are reincorporated at the first phase of the production cycle. It proposes to recover and restore used products, components and materials applying strategies such as reuse, repair and remanufacturing [4].

Remanufacturing is an industrial recovery process of used product which guarantees that a recovered product offers at least the same functionalities as a new one [5]. To achieve this goal, it goes through different stages that involves dismantling the product, restoring and replacing components and testing the individual parts and the whole product to ensure that it is within its original design specifications.

Taking into account the aforementioned, it is important to note that the focus should not only be on reducing economic costs of the production process but also on minimizing the negative impact on the environmental of their activities. This can be achieved by redesigning the production cycle of factories to focus on more environmentally friendly strategies such as collecting and remanufacturing used products.

Regarding production planning, we note that Wagner and Whitin [2] were the first to suggest an efficient algorithm for the ELSP. It is based on a dynamic programming approach of computational complexity $O(n^2)$, with n the number of periods. Zangwill [6] extended the algorithm for the case of general concave costs and Hanafizadeh et al. [7] extended with uncertain costs. In 1993, Aggarwal and Park [8] developed a more efficient algorithm of $O(n \log n)$ time.

A relative recently extension of the ELSP is to consider the remanufacturing of used products returned to the origin in order to satisfy the demand requirements. This problem extension is known in the literature as the Economic Lot Sizing Problem with Remanufacturing (ELSR). Teunter et al. [9] analyze this problem, suggesting a Mixed Integer-Linear Programming (MILP) formulation for the cases of joint and separate set-up scheme. In addition, the Silver-Meal (SM), Minimum Unit Cost (LUC) and Fragmented Period Balancing (PPB) heuristics are adapted for the problem. Piñeyro and Viera [10] tackle the ELSR with disposal options. A Basic Tabu Search (BTS) based-on procedure is proposed and evaluated. In Piñeyro and Viera [11] the performance of the BTS procedure is improved by means of applying a property on the form of the ELSR optimal solutions.

Absi et al. [12] and Retel Helmrich et al. [13], describe that in recent years, a significant effort has been made to mitigate the environmental impact of industrial processes. For instance, the United Nations Kyoto Protocol in 1998 [14], and the European Commission's emissions trading legislation in 2010 [15]. In Retel Helmrich et al. [13], the emission in both the set-up and the inventory holding costs are studied for the ELSP. To solve the problem, they suggest a Lagrangean heuristic and a Polynomial-Time Approximation Scheme (FTPAS) based-on algorithm.

The Cap-and-Trade emerged as a public policy to counteract CO_2 emissions, offering economic incentives for those who manage to reduce them. Benjaafar et al. [16] and Akbalik and Rapine [17] suggest and study models for exploring this concept. In Benjaafar et al. [16] and Yuan et al. [18], the concept of Certified Emission Reduction (CER) is also incorporated in order to reduce the carbon emissions.

The problem of lot-sizing that incorporates remanufacturing options under a carbon emission constraint is considered by Zouadi et al. [19, 20]. Piñeyro and Viera [21] consider the ELSR with recovery targets established as a percentage of the total returns that must be remanufactured. Establishing a recovery target may be a mechanism to reduce the negative impact of the new item manufacturing activity. Rapine et al. [22] also tackle a production system with capacity constraints and environmental considerations. The objective is to minimize the sum of all the costs involved and the use of energy established as a non-linear function. Giglio et al. [23] address an integrated lot sizing and energy-efficient job shop scheduling problem, minimizing the sum of the economic costs and the energy costs related to the utilization of machines and processing times. Finally, Heck and Schmidt [1] identify three relevant factors to minimize the environmental impact in a production system: energy use, carbon emissions and water consumption. A mathematical model is defined with an objective function that includes the cost of energy, emissions and water usage in addition to the economic costs of production.

In this paper we propose a MILP formulation for the ELSR considering environmental costs in addition to the traditional economic costs. The main difference with the problem addressed in Zouadi et al. [19, 20] is that we consider not only emissions, but also water and energy consumption. In addition, we relax the upper bounds on the emissions, since it is considered as part of the environmental costs.

For this ELSR extension, three heuristic procedures based on the Tabu Search metaheuristic are suggested and evaluated by means of a benchmark set of ELSR instances adapted to this problem. The suggested procedures are based on the BTS procedure introduced in Piñeyro and Viera [10] for the ELSR, extending it to consider environmental costs as well as other strategies for the exploration phase.

The rest of the paper is organized as follows. Section 2 provides the problem definition and the mathematical model for the ELSR extension under consideration. Section 3 addresses the description of the solution procedures suggested for the problem. The numerical experimentation and the analysis of the results obtained are provided in Section 4. Conclusions and possible directions for future research are given in Section 5.

2 Problem definition

We address a hybrid production-remanufacturing system of a single product in which the demand must be satisfied on time by either the production of new items or remanufacturing used ones returned to the origin, i.e., remanufactured products look as-good-as new. Henceforth, the terms return and used product, as well as production and manufacturing, are used interchangeably. Demand and returns values are assumed non-negative integers known in advance for each one of the periods within the finite planning horizon. Economic and environmental costs are assumed for manufacturing and remanufacturing, as well as for the inventory of serviceable and used products. Three types of environmental costs are considered: water consumption costs, energy consumption

costs and emissions costs. Set-up costs are assumed for both manufacturing and remanufacturing, and linear costs for holding inventory of both used and serviceable products. The objective is to determine the quantities to produce and remanufacture at each period in order to minimize the sum of the economic and environmental costs.

The notation used for the problem is listed below.

- Parameters:
  - n: number of periods, with $n > 0$.
  - $T = \{1, ..., n\}$: set of periods within the planning horizon.
  - D_t: serviceable items demanded in period $t \in T$.
  - R_t: used items returned in period $t \in T$.
  - h_t^r: economic unit cost of holding used inventory in period $t \in T$.
  - h_{at}^r: water consumption unit cost of holding used inventory in period $t \in T$.
  - h_{ct}^r: emissions unit cost of holding used inventory in period $t \in T$.
  - h_{et}^r: energy unit cost of holding used inventory in period $t \in T$.
  - h_t^s: economic unit cost of holding serviceable inventory in period $t \in T$.
  - h_{at}^s: water consumption unit cost of holding serviceable inventory in period $t \in T$.
  - h_{ct}^s: emissions unit cost of holding serviceable inventory in period $t \in T$.
  - h_{et}^s: energy unit cost of holding serviceable inventory in period $t \in T$.
  - K_t^m: economic set-up cost for manufacturing in period $t \in T$.
  - K_{at}^m: water set-up cost for manufacturing in period $t \in T$.
  - K_{ct}^m: emissions set-up cost for manufacturing in period $t \in T$.
  - K_{et}^m: energy set-up cost for manufacturing in period $t \in T$.
  - K_t^r: economic set-up cost for remanufacturing in period $t \in T$.
  - K_{at}^r: water set-up cost for remanufacturing in period $t \in T$.
  - K_{ct}^r: emissions set-up cost for remanufacturing in period $t \in T$.
  - K_{et}^r: energy set-up cost for remanufacturing in period $t \in T$.
  - M: big number.
- Decision variables:
  - I_t^s: inventory level of serviceable products in period $t \in T \cup \{0\}$.
  - I_t^r: inventory level of returns in period $t \in T \cup \{0\}$.
  - x_t^m: number of items to manufacture in period $t \in T$.
  - x_t^r: number of items to remanufacture in period $t \in T$.
  - y_t^m: equal to 1 if there is manufacturing in period $t \in T$, 0 otherwise.
  - y_t^r: equal to 1 if there is remanufacturing in period $t \in T$, 0 otherwise.

We refer to the hybrid system described above as the Economic Lot-Sizing Problem with Remanufacturing and Environmental Costs (ELSR-EC). It can be formulated as the following MILP, extending those suggested for the ELSR in [9, 11]:

$$\min \sum_{t \in T} \Big\{ \left(K_t^m y_t^m + K_t^r y_t^r + h_t^s I_t^s + h_t^r I_t^r\right) + \left(K_{et}^m y_t^m + K_{et}^r y_t^r + h_{et}^s I_t^s + h_{et}^r I_t^r\right) + \left(K_{ct}^m y_t^m + K_{ct}^r y_t^r + h_{ct}^s I_t^s + h_{ct}^r I_t^r\right) + \left(K_{at}^m y_t^m + K_{at}^r y_t^r + h_{at}^s I_t^s + h_{at}^r I_t^r\right) \Big\} \quad (1)$$

subject to:

$$I_t^s = I_{(t\text{-}1)}^s + x_t^r + x_t^m - D_t, \quad \forall t \in T \tag{2}$$

$$I_t^r = I_{(t\text{-}1)}^r + R_t - x_t^r, \quad \forall t \in T \tag{3}$$

$$x_t^m \leq M y_t^m, \quad \forall t \in T \tag{4}$$

$$x_t^r \leq M y_t^r, \quad \forall t \in T \tag{5}$$

$$I_0^s = I_0^r = 0 \tag{6}$$

$$y_t^m, y_t^r \in \{0, 1\}, \quad \forall t \in T \tag{7}$$

$$x_t^m, x_t^r, I_t^s, I_t^r \geq 0, \quad \forall t \in T \tag{8}$$

Objective function (1) is composed by four components: economic costs, energy consumption costs, emissions costs and water consumption costs. Equations (2) and (3) are the inventory balance equations for serviceable and used products, respectively. Constraints (4) and (5) state that the binary variables related to the set-up costs for production and remanufacturing must be equal to 1 if a positive amount is produced or remanufactured, respectively. Constraint (6) establishes that the initial inventory level for both serviceable and used products is assumed equal to zero. Finally, constraints (7) and (8) define the domain for the decision variables of the problem.

3 Heuristic procedures for the ELSR-EC

In this section we present the main solving procedure and its variants, suggested for the ELSR-EC. The procedure TS-EC (Tabu Search with Environmental Costs) is based on the Tabu Search metaheuristic (Glover et al. [24]). This metaheuristic is an iterative exploration process based on information stored in memory (tabu list) to allow to escape from local optimal of optimization problems. In the following subsections the different components of TS-EC will be explained. This procedure can be considered an extension of the BTS procedure proposed by Piñeyro and Viera [10] for the ELSR.

3.1 TS-EC procedure

A feasible solution of the ELSR-EC is represented as a pair of (0,1) n-tuples, one for indicating the positive periods of remanufacturing and the other for the positive periods of manufacturing. A value 1 in position t of the remanufacturing (manufacturing) in the n-tuple means remanufacturing (manufacturing) can be positive in period t, with $1 \leq t \leq n$. On the other hand, a value 0 in position t means remanufacturing (manufacturing) must be zero.

The TS-EC procedure consists of the following phases:

- **Initial phase**: the initial n-tuple of the remanufacturing plan is generated.

- **Generation phase**: given the *n*-tuple of the remanufacturing periods, the remanufacturing amounts are determined and then, the optimal production plan (periods and quantities) is obtained.
- **Exploration phase**: given the feasible ELSR-EC solution from the previous phase, a new solution is sought among its neighbors, with lower ecological and economic costs than the given (or current) solution.

For the initial phase, we use a value of zero for every position of the *n*-tuple of the remanufacturing plan, i.e. zero remanufacturing. Given the *n*-tuple of the remanufacturing plan, the generation phase is performed in order to determine a feasible solution for the ELSR-EC. The remanufacturing plan is determined according to the following rule also used in [10]:

$$x_i^r = min\ \{I_{i-1}^r + R_i,\ D_{i,(j-1)}\}\ \forall 1 \leq i < j \leq n+1 \tag{9}$$

$$D_{i,(j-1)} = \sum_i^{j-1} D_k \tag{10}$$

Equation (9) means that the remanufacturing quantity of a period *i* is determined as the minimum between the number of available returns in period *i* and the accumulated demand, described in (10), until the preceding period of the period *j* fixed as the next period of positive remanufacturing. We note that the optimal production plan can be obtained from a given remanufacturing plan [10]. The algorithm of Wagner and Whitin [2] was adapted to consider the initial inventory of serviceable products and the environmental costs of the production activity.

Finally, the exploration phase is performed with the aim to improve the feasible solution of the ELSR-EC obtained from the generation phase. First the neighbors of the remanufacturing *n*-tuple are determined by means of a Hamming distance of 1 (swap moves). It is checked that each neighbor does not belong to the tabu list. We consider a limited size tabu list managed according to the FIFO rule (First in First Out). A new candidate solution for the problem is determined using the procedure of the generation phase. The exploration phase runs until the stop condition is reached: the number of iterations is greater than a certain maximum value. The solution with the lowest economic and environmental cost of all the evaluated solutions, is returned.

3.2 TS-EC variants

In order to make the exploration phase of the TS-EC more diverse, we develop two variants of the procedure by means of the jump transformation defined as follows. Given a feasible solution of the ELSR-EC, a jump is defined as a shift of certain number of components of the *n*-tuple of its remanufacturing plan, from 0 to 1 or vice versa. The following jump transformations are used in this paper:

- Negative: all components from 1 to *n* of the remanufacturing *n*-tuple are shifted.
- Random: a random number of the components of the remanufacturing *n*-tuple are shifted.

We refer as TS-ECNO and TS-ECRO to the TS-EC variants with the negative and the random jump transformations, respectively. The following pseudocode presents an outline of the new procedures.

```
jumpCount = 0;
remanufacturingTuple = zeroTuple;
solution = TS-EC(remanufacturingTuple);
while (jumpCount < jumpCountMax) {
  remanufacturingTuple = solution.remanufacturingTuple()
  if (variant == TS-ECNO) {
    transformedTuple = Negative(remanufacturingTuple);
  }
  if (variant == TS-ECRO) {
    transformedTuple = Random(k, remanufacturingTuple);
  }
  solution = TS-EC(transformedTuple);
  jumpCount ++
}
```

We note that the Random () function in the pseudocode of above receives the number k of components of the remanufacturing n-tuple to be shifted. The position of each component is determined randomly.

4 Numerical experimentation

In this section we provide the results of the numerical experimentation carried out to evaluate the performance of the heuristic procedures presented in the previous section. The cost gap between the solution obtained from the heuristics and that from AMPL/CPLEX, is calculated as follows:

$$cost\ gap = \frac{heuristic\ cost - exact\ method\ cost}{exact\ method\ cost} \times 100 \tag{11}$$

The parameter values were generated according to a uniform distribution (UD), considering the ranges suggested by Retel Helmrich et al. [13]. We consider two different scenarios for returns and set-up costs of remanufacturing, “Low” and “High”. In order to facilitate the comparison of the results, the unit production and remanufacturing costs are assumed zero.

- Demand (D_t): UD(100, 200).
- Returns (R_t): UD(0, 100) and UD(100, 200).
- Set-up cost for production (K_t^m,$\hat{K}_{at}^m$,$\hat{K}_{ct}^m$,$\hat{K}_{et}^m$): UD(2500, 7500).
- Set-up cost for remanufacturing (K_t^r,$\hat{K}_{at}^r$,$\hat{K}_{ct}^r$,$\hat{K}_{et}^r$): UD(500, 1500) and UD(2500, 7500).
- Inventory cost for final products (h_t^s,$\hat{h}_{at}^s$,$\hat{h}_{ct}^s$,$\hat{h}_{et}^s$): UD(10, 20).
- Inventory cost for returns (h_t^r,$\hat{h}_{at}^r$,h_{ct}^r,$\hat{h}_{et}^r$): UD(0, 10) y DU(10, 20).

We note that there are 512 different configurations of parameter values. For each configuration we generate 10 different instances, which results in 5,120 instances in total. The number of periods (n) is equal to 20 for all the instances.

It is important to note that TS-EC and TS-ECNO are deterministic, whereas TS-ECRO can give different results depending on the executions since the periods to be shifted are chosen randomly. Therefore, for the TS-ECRO we take the average value of three runs for each one of the instances.

There are also certain parameters that are specific to the heuristics, which are listed below:

- MAX_ITER: number of iterations for the exploration phase.
- MAX_JUMPS: number of jumps transformation to be performed.
- LIST_SIZE: number of n-tuples to be stored in the tabu list.
- RANDOM_NUM: number of periods to be shifted at the remanufacturing n-tuple.

In Table 1 we provide the values chosen for the parameters of the heuristics. To achieve this, a preliminary study was carried out in 512 instances, comparing the results against CPLEX solver.

Table 1. Heuristic parameter values for $n = 20$.

	TS-EC	TS-ECNO	TS-ECRO
MAX_ITER	50	50	50
MAX_JUMPS	-	2	4
LIST_SIZE	1,000,000	1,000,000	1,000,000
RANDOM_NUM	-	-	16

All the numerical experiments were carried out on a 2.81Hz Windows 10 i7-7700HQ laptop, with 16GB RAM.

4.1 Performance analysis for $n = 20$

Tables 2 and 3 show the results for the costs gap and runtimes (in milliseconds) of the numerical experimentation. The first three columns in Table 1 describe the scenario (for example: Setup – Economic – High scenario). Then, there are columns for reporting the average, median, standard deviation and maximum values for the heuristics. Table 3 also includes the runtimes of CPLEX.

Table 2. Cost gaps for $n = 20$.

			Average			Median			Standard deviation			Maximum		
			TS-EC	TS-ECNO	TS-ECRO	TS-EC	TS-ECNO	TS-ECRO	TS-EC	TS-ECNO	TS-ECRO	TS-EC	TS-ECNO	TS-ECRO

		High	1.0%	0.6%	0.6%	0.5%	0.4%	0.3%	2.0%	0.8%	0.7%	31.6%	10.6%	10.6%

From Table 2 we can observe that the solutions found by the heuristics are similar to those found by CPLEX, with an average gap less than 1.5%. Then, we can conclude that the three heuristics are competitive with CPLEX.

Regarding the standard deviation in Table 3, we can note that the solutions found by CPLEX show a greater dispersion in terms of running time than the solutions from the heuristics.

Table 3. Running times (ms) for $n = 20$.

			Average				Median				Standard deviation				Maximum

From Tables 2 and 3, we conclude that TS-ECNO and TS-ECRO variants outperform the TS-EC original heuristic in terms of cost gaps. In addition, we note that in average, TS-ECNO achieves the best results in terms of both, cost gaps and running times. In general, we also can conclude that the three heuristics are competitive compared to the CPLEX solver.

4.2 Cost weighting analysis

We note that the objective function of ELSR-EC considers the sum of the economic and environmental costs. However, environmental costs are composed by set-up costs

for emissions, energy and water consumptions. In this section we update the costs as follows: environmental costs are multiplied by α and the economic costs by β, with $0 \leq \alpha, \beta \leq 1$, in order to analyze the solutions under different weights on the cost components of the objective function. We consider 512 instances (one per configuration) and the TS-ECNO heuristic.

In Table 4 we summarize the results obtained. First column presents the different weights of the costs considered. The rest of the columns present the difference between the economic cost of the weighted function and the economic cost of the original function for all the measurements (average, median, standard deviation and maximum). The same is shown for the environmental costs.

Table 4. Weighted cost results for TS-ECNO compared to AMPL/CPLEX.

Weights	Average		Median		Standard deviation		Maximum	
	Gap cost Econ. (%)	Gap cost Env. (%)	Gap cost Econ. (%)	Gap cost Env. (%)	Gap cost Econ. (%)	Gap cost Env. (%)	Gap cost Econ. (%)	Gap Cost Env. (%)
α = 0, β = 1	-7.759%	13.874%	-6.977%	9.585%	6.380%	18.980%	-42.854%	197.415%
α = 1/3, β = 1	-4.604%	3.199%	-3.052%	1.810%	5.529%	4.659%	-32.299%	49.587%
α = 1, β = 0	6.979%	-1.026%	4.252%	-0.475%	9.551%	1.749%	95.380%	-13.794%

For the case ($\alpha = 0, \beta = 1$), only the economic costs are minimized. Analyzing the results in the average case, we note that the environmental costs increase around 14% with a maximum increase of 197.4%. Therefore, we can conclude that not including environmental costs in the objective function can cause a significant ecological impact. On the other hand, the economic cost in average decreases around 8% compared to the problem with the original cost function, i.e., $\alpha = \beta = 1$.

Since the environmental costs have three components (water, energy and emission), the case ($\alpha = 1/3$, $\beta = 1$) is intended to balance the weight of the three environmental aspects and of the economic costs. We note that the average of environmental cost increases only 3.2% with respect to the original objective function. In the opposite direction, is observed for the economic costs. However, the impact of reducing the weight of the environmental costs may be significant as it can be seen in the maximum gaps.

Finally, for the last scenario ($\alpha = 1$, $\beta = 0$) with only environmental costs in the objective function, we note the economic costs increase in average near to 7%, but the maximum gap is 95%. In addition, the benefits on the environmental side are only 1%.

4.3 Performance analysis for $n = 70$

Given the good performance obtained for the three heuristics for the case of 20 periods, we decided to evaluate them for large instances of 70 periods. Because of the size of the problem with 70 periods, we consider only 14 instances chosen arbitrary from the 512 configurations defined at the beginning of Section 4. The values of the parameters for the heuristic procedures are reported in Table 5 (the format is the same as Table 1).

Table 5. Heuristic parameter values for $n = 70$.

	TS-EC	TS-ECNO	TS-ECRO
MAX_ITER	15	15	15
	25	25	25
	35	35	35
	45	45	45
MAX_JUMPS	-	2	4
LIST_SIZE	1,000,000	1,000,000	1,000,000
RANDOM_NUM	-	-	16

In Table 6 we present the results obtained from the heuristics for the 14 large instances. First column indicates the name of the solving procedure and the second column the maximum number of iterations for the heuristic procedures. The rest of the columns are for the cost gaps and runtimes (average, median, deviation and maximum).

Table 6. Cost gaps and runtimes for $n = 70$.

	Iterations	Average		Median		Standard deviation		Maximum	
		Cost gap (%)	Runtime (m)	Cost gap (%)	Runtime (m)	Cost gap (%)	Runtime (m)	Cost gap (%)	Runtime (m)
CPLEX	-	0.000%	2.543	0.000%	0.684	0.000%	4.443	0.000%	15.087
TS-EC	15	12.945%	0.107	8.186%	0.103	18.098%	0.007	79.969%	0.123
	25	3.544%	0.207	2.183%	0.206	5.037%	0.008	22.270%	0.227
	35	2.350%	0.254	1.876%	0.253	2.165%	0.009	10.129%	0.276
	45	2.248%	0.440	1.876%	0.439	1.828%	0.004	8.706%	0.452
TS-ECNO	15	8.365%	0.372	8.186%	0.373	2.698%	0.010	12.000%	0.386
	25	2.826%	0.536	2.183%	0.534	1.003%	0.007	5.529%	0.555
	35	2.130%	0.764	1.876%	0.757	1.394%	0.038	6.833%	0.900
	45	2.058%	1.104	1.876%	1.103	1.204%	0.005	5.941%	1.120
TS-ECRO	15	1.880%	0.619	1.751%	0.623	0.681%	0.021	3.850%	0.641
	25	1.251%	1.439	1.182%	0.936	0.624%	0.029	3.264%	1.003
	35	1.204%	1.439	1.206%	1.254	0.724%	0.669	3.474%	3.941
	45	1.121%	1.766	0.971%	1.766	0.718%	0.031	3.496%	1.833

Considering the average values of Table 6 we can conclude that the suggested heuristics are competitive with CPLEX. In particular, for both the 35 and 45 iterations cases, we can observe that TS-ECRO achieves the lowest cost gaps (1.204% for 35 iterations and 1.121% for 45 iterations) in a less running time than CPLEX (1.439 and 1.766 versus 2.543 minutes, respectively).

5 Conclusions and future research

In this paper we address the economic lot-sizing problem with remanufacturing, considering environmental costs in addition to the traditional economic costs. We provide a MILP formulation for the problem and suggest three heuristic procedures based on the Tabu Search metaheuristic to solve it. To evaluate their performance, we compare them against AMPL/CPLEX, considering both costs and running times of the solutions.

Although the three heuristic procedures, TS-EC, TS-ECNO and TS-ECRO, show a good performance compared to the CPLEX solver, we note that for small and medium size instances, TS-ECNO achieves the best performance, considering the balance between runtime and cost gaps. On the other hand, for large instances, TS-ECRO achieves the best performance probably due to its random nature. In particular, we note that for the large instances the average runtimes for all procedures are significantly lower than those of CPLEX. In addition, the runtimes of the heuristic procedures are more stable, since their standard deviation is less than that obtained from the solver.

In order to improve the performance of heuristic procedures, we can modify the stop condition considering a maximum number of iterations without improvements instead of the total number of iterations as it is currently done. Another possible way to improve the procedures may be to analyze the form of the optimal solutions of the ELSR-EC as in Piñeyro and Viera [11] for the ELSR. Regarding the model, we observe that the objective function considered is the sum of the economic and environmental costs. A more realistic approach would be to consider a multi-objective function or even a multi-level model to better represent the relationship between economic and environmental costs.

Abstract. We address an extension of the discrete lot-sizing and scheduling problem in which the demand of products can be also satisfied by remanufacturing used products returned to the origin. A mixed-integer linear programming formulation is provided for the problem, assuming dynamic demand and returns values, and time-invariant costs of setup and holding inventory. We then present a numerical experimentation carried out with the mathematical model for the case of a single product, in order to evaluate the efficiency in both costs and solving times compared to the traditional problem without returns. From the results obtained we conclude that the problem with recovery options can lead to economic benefits only under certain assumptions on the costs and amounts of returns. In addition, according to the runtimes obtained for large instances of the problem, it seems to be much more difficult to solve than its traditional version without returns.

Keywords: lot-sizing, scheduling, remanufacturing, mathematical programming, optimization

1 Introduction

The discrete lot-sizing and scheduling problem (DLSP) refers to the problem of simultaneously determining the lots and sequence of production for a set of products, in order to meet the demand requirements on time, minimizing the sum of production and inventory holding costs. Unlike other lot-sizing problems, in the DLSP only one item can be produced at each period and the production process runs at full capacity, i.e., small bucket periods and all-or-nothing production policy are assumed. Therefore, the quantity of production in a period established as a positive production period is determined based on a certain production speed

expressed in units per period. In addition, setup costs are only incurred when there is product changeover, i.e., configuration costs of the production line are only incurred at the beginning of the production process of a product.

A mixed-integer linear programming (MILP) and a heuristic solving approach for the DLSP in the case of a single machine is proposed in [3]. In [4] the DLSP with sequence-dependent setup costs is formulated and analyzed. Salomon et al. in [17] present a classification scheme and complexity results for the DLSP. In particular, they demonstrated that the DLSP with stationary costs, positive setup costs and single machine is NP-hard. However, they note that the DLSP for a single product can be efficiently solved as in [8] and [24]. Several extensions and solving approaches have been proposed in the literature for the DLSP, such as [23] for costs with non-speculative motives and [7] for start-up times and backlogging in the context of a tire curing scheduling problem. More recently, the DLSP with sequence-dependent changeover costs and time is addressed in in [5]. Bi-objective formulations for the DLSP considering carbon emissions and renewable energy are presented in [10]. We refer the readers to [1] and [25] for recent surveys about the DLSP and extensions.

In recent years, the circular economy (CE) paradigm has emerged as an alternative to face the negative impact on the environment of the traditional linear model of producing, consuming and disposing [21]. As a recovery option, remanufacturing can be considered a critical component of the CE as it attempts to maintain the value of used products (also called cores or returns) and to reduce the use of raw material and energy [9], thus achieving a win-win-win situation for producers, consumes and environment. Remanufacturing is an industrial process in which it is warrantied that a used product is returned to its original condition or even better. It often involves inspection, sorting, disassembling, cleaning, testing, reprocessing and reassembling tasks. Remanufacturable products include automotive parts, electric home appliances, personal computers, cellular phones, cameras, vending machines, among others [11]. In the field of production planning, we can find the seminal works of [15], [16] and [26] that extend the traditional economic lot-sizing problem (ELSP) in order to include returns flow and remanufacturing process. Teunter et al. [22] introduce the economic lot-sizing problem with remanufacturing (ELSR) with either joint or separate setup scheme. They provide an efficient algorithm for the joint case and extend the Silver-Meal heuristic for the problem. In [12] consider the ELSR with disposal of returns and in [18] suggest several improvements for the extended Silver-Meal heuristic. In [2], [19], [13] are suggested and evaluated different solving procedures for the ELSR based on metaheuristic approaches, and [14] considers the ELSR with recovery targets. We refer to [21] for a recent survey about production planning with recovery options.

In this paper, we extend the DLSP in order to include the returns flow, and assuming that demand can be also satisfied by remanufacturing used products. We refer to this problem extension as the discrete lot-sizing and scheduling problem with remanufacturing (DLSR). We provide a MILP formulation for the problem and present and analyze the results of a numerical experimentation

carried out in order to evaluate the efficiency in both costs and solving time of this hybrid production-remanufacturing system in the case of a single product. As far as we know, this DLSP extension has not been considered in the literature before. However, we note that there are some works that combine scheduling and remanufacturing, but for different problem assumptions [27], [6], [20].

The remainder of this paper is organized as follows. In Section 2 we present the description and the MILP formulation suggested for the problem under consideration. Section 3 provides the results and the analysis of the numerical experimentation carried out in order to evaluate the efficiency of the DLSR for the case of a single product. Finally, in Section 4 we present the conclusions and some possible directions for future research.

2 Problem description and formulation

The problem tackled in this paper can be stated as follows. We address a dynamic hybrid production-remanufacturing system with a single machine for processing $J > 0$ products under all-or-nothing production policy and over a finite planning horizon $T > 0$. Small-bucket periods are assumed. Therefore, only one product can be produced or remanufactured, but not both in the same period. The production and remanufacturing speeds for each product j, p_j and r_j respectively, are expressed as unit per period. Demand for a product j in a period t must be satisfied on time (backlogging is not allowed) from produced or remanufactured products generated in the same period (zero lead-time is assumed) or in a previous period and held in the inventory of serviceable products. Demand and returns values are assumed known in advance for each product and period over the planning horizon. Production and remanufacturing setup costs are incurred when there is product changeover. There are also linear costs for carrying on one unit of serviceable or used product from one period to the next one. Setup and inventory holding costs are assumed known and time-invariant. The objective is to determine the lots and sequence of products to be produced and remanufactured in order to satisfy the demand requirements on time, minimizing the sum of the costs involved.

Below we present the notation used for the problem from here and throughout the rest of the paper.

Sets and indices:

J : Number of products, with index $j \in \{1, ..., J\}$.
T : Number of periods, with index $t \in \{0, 1, ..., T\}$.

Parameters:

D_{jt} : Demand of product j in period $t > 0$.
R_{jt} : Returns of product j available in period $t > 0$.
K_j^p : Production setup cost of product j.
K_j^r : Remanufacturing setup cost of product j.
h_j^s : Holding cost for serviceable product j per unit and per period.
h_j^u : Holding cost for used product j per unit and per period.
p_j : Production speed for product j (units per period).
r_j : Remanufacturing speed for product j (units per period).

Variables:

I_{jt}^s : Inventory of serviceable product j at the end of period t.
I_{jt}^u : Inventory of used product j at the end of period t.
y_{jt}^p : $y_{jt}^p = 1$ indicates that product j is produced in period t;
$y_{jt}^p = 0$, otherwise.
y_{jt}^r : $y_{jt}^r = 1$ indicates that used product j is remanufactured in period t;
$y_{jt}^r = 0$, otherwise.
z_{jt}^p : $z_{jt}^p = 1$ indicates a production setup for product j in period $t > 0$;
$z_{jt}^p = 0$, otherwise.
z_{jt}^r : $z_{jt}^r = 1$ indicates a remanufacturing setup for product j in period $t > 0$;
$z_{jt}^r = 0$, otherwise.

Based on the notation of above, the DLSR can be formulated as the following MILP. We note that it can be considered an extension of that introduced in [8] and [24] for the DLSP.

$$\min \quad \sum_{j=1}^{J}\sum_{t=1}^{T}(K_j^p z_{jt}^p + K_j^r z_{jt}^r + h_j^s I_{jt}^s + h_j^u I_{jt}^u) \tag{1}$$

$$\text{s.t.} \quad I_{jt}^s = I_{j(t-1)}^s + p_j y_{jt}^p + r_j y_{jt}^r - D_{jt}, \quad \forall j, t > 0 \tag{2}$$

$$I_{jt}^u = I_{j(t-1)}^u + R_{jt} - r_j y_{jt}^r, \quad \forall j, t > 0 \tag{3}$$

$$\sum_{j=1}^{J}(y_{jt}^p + y_{jt}^r) \leq 1, \quad \forall t > 0 \tag{4}$$

$$z_{jt}^p = y_{jt}^p - y_{j(t-1)}^p, \quad \forall j, t > 0 \tag{5}$$

$$z_{jt}^r = y_{jt}^r - y_{j(t-1)}^r, \quad \forall j, t > 0 \tag{6}$$

$$I_{j0}^s = I_{j0}^u = y_{j0}^p = y_{j0}^r = 0, \quad \forall j \tag{7}$$

$$I_{jt}^s, I_{jt}^u \geq 0, \quad \forall j, t \tag{8}$$

$$y_{jt}^p, y_{jt}^r, z_{jt}^p, z_{jt}^r \in \{0, 1\}, \quad \forall j, t \tag{9}$$

The objective function (1) minimizes the sum of setup and inventory holding costs. Constraints (2) and (3) are the inventory balance equations for serviceable and used products, respectively. Constraints (4) establish that: i) only one product can be produced or remanufactured in certain period; ii) production and remanufacturing can not be carried out in the same period. Constraints (5) and (6) are for establishing the production and remanufacturing setup cost incurred when there is product changeover, respectively. The constraints (7) mean that the initial inventory level for all products is assumed zero and that the system is initially idle. Finally, (8) and (9) are the domain constraints for the decision variables.

3 Numerical experimentation

In this section we provide the results and the analysis of the numerical experiments carried out to evaluate the mathematical model suggested for the DLSR. Specifically, we are interested in compare the efficiency in both costs and solving time for the problem with and without returns, i.e, the DLSR and the DLSP. We note that the MILP of Section 2 in which the parameters, variables and specific constraints related to returns are removed, corresponds to the formulation of the DLSP.

To facilitate the understanding of the results and to make a more effective comparison, we consider for the experiments the case of a single product ($j = 1$).

3.1 Experiments design

The instances were generated based on the benchmark set introduced in [22] and [18] for the ELSR, also used in [2], [19], [13] and [14]. All them have a

planning horizon T of 22 periods (workdays of a month). Demand values D_{1t} were generated according to a normal distribution with mean 100 and 20% of coefficient variation. Returns R_{1t} were also generated using a normal distribution with means 50, 70 and 100, and 20% of coefficient variation. The setup cost of production K_1^p is set to 2000 and the setup cost of remanufacturing K_1^r can be 200, 500 and 2000. The unit cost for holding inventory of serviceable products h_1^s is set to 1 and for used products h_1^u can be 0.2, 0.5 and 0.8. Production speed p_1 is set to 200 units per period, and the remanufacturing speed r_1 can take values on 200, 300 and 400 units per period. Note that, as is to be expected in practice, it is assumed that remanufacturing costs are at most equal to production costs and that remanufacturing speed is at least equal to production speed. We generate 10 instances for each on of the 3^4 configurations, that is 810 instances in total. In addition, to evaluate the solving time, we generate one instance for each configuration, with planning horizons of 22, 44, 66, 88, 110 and 132 periods, that is $81 \times 6 = 486$ instances in total.

The model was coded in AMPL and solved for all the instances of above with CPLEX 12.9.0.0 with a time limit of 1800 seconds, on a PC with 8 CPUs Intel Core i7-6700 3.40GHz, 64-bit, 24GB of RAM and CentOS Linux 7.

3.2 Analysis of results for instances with $T = 22$

Next, we present and analyze the results obtained for the instances with a planning horizon of $T = 22$ periods. The values shown in Table 1 are the average cost, the standard deviation and maximum cost of the optimal solutions obtained with CPLEX for the DLSR and DLSP. We decided not to report the runtimes, since they were very low for both problems, less than half a second for all the 810 instances. In the first row of the table, labeled as *"All instances"*, we show the average cost considering all the instances, which is 12480.1 for the DLSR and 10828.9 for the DLSP. This represents around of 15% increase in the costs for the DLSR in average. However, we can note that in the cases of low-cost returns ($K_1^r = 200$ or $h_1^u = 0.2$), the costs are in average a little more favorable for the DLSR. The average costs of these cases are highlighted in the table (underlined and in bold). In fact, for each one of the 90 instances with $K_1^r = 200$ and $h_1^u = 0.2$, we want to remark that the cost of the DLSR optimal solutions is lower than the cost of the DLSP optimal solutions, even reaching differences of more than 35% in favor of the DLSR. We also note that the total number of instances for which the cost is favorable for the DLSR is 255, that is 30% of the total instances. On the other hand, we note that the maximum gap between the average costs of the DLSR and DLSP is for the cases of high-cost returns ($K_1^r = 2000$ and/or $h_1^u = 0.8$).

In the cases of variations on the average quantity of returns (R_{1t}), we note that they do not have a significant impact on the cost gaps. However, we note a favorable trend to the DLSR as the amount of returns increase, as it can be noted for the case of large returns ($R_{1t} = 100$). The opposite behaviour can be observed for the remanufacturing speed (three last rows of Table 1): as the remanufacturing speed increases, also do the average cost gap between DLSR and

DLSP. Therefore, it would be more economically convenient to consider similar speeds for production and remanufacturing, although in fact the remanufacturing speed could be higher, as it often requires less labor effort, materials, and energy.

In Table 1, the higher standard deviation and maximum values obtained for the DLSR compared to the DLSP, may be due to the fact that the variations are in the parameters related to the returns, which do not affect the DLSP. However, this appreciable dispersion in the costs of the DLSR optimal solutions observed for all the instances, would show that the variation in the parameter values has a significant impact on the efficient resolution of the problem.

Table 1. Summary of results for the 810 instances with $T = 22$ for DLSR and DLSP. The columns represent the average, standard deviation and maximum value of the optimal solutions obtained with CPLEX.

		Average		***Stand. desv.***		***Maximum***	
		DLSR	**DLSP**	**DLSR**	**DLSP**	**DLSR**	**DLSP**
All instances		12480.1	10828.9	2858.7	413.6	21086.2	12065.0

h_1^u	**0.2**	**10600.6**	**10804.5**	2116.3	393.0	15177.6	11794.0
	0.5	12582.6	10850.2	2483.1	442.9	17746.0	12065.0
	0.8	14257.1	10831.9	2684.7	403.4	21086.2	11930.0
r_1	**200**	11519.7	10846.1	2672.3	419.6	17711.6	12065.0
	300	12610.2	10819.1	2825.5	433.9	20403.2	12007.0
	400	13310.3	10821.5	2796.2	386.9	21086.2	11930.0

The cases in which the DLSR obtained lower costs than DLSP, that is, $K_1^r = 200$ and $h_1^u = 0.2$, are presented in more detail in Tables 2 and 3, respectively.

Table 2 shows the average cost of the optimal solutions for the DLSR and DLSP for the instances with $K_1^r = 200$. The rest of the parameters (R_{1t}, h_1^u and r_1) vary as described in Section 3.1. In column "Gap" we report the difference in percentage between the average costs of the optimal solutions determined as: $100 \times (DLSR_cost - DLSP_cost)/DLSP_cost$). From Table 2 we first note that the DLSR average costs are lower than DLSP in most cases (negative values in the Gap column). In terms of R_{1t}, it can be seen that as the value of returns increases, the cost of the DLSR optimal solutions decreases, reaching a percentage gap near to -14%. For the cases of h_1^u, we note that the sensitivity of the DLSR is significant with respect to this parameter, since the cost gaps vary from -19.3% ($h_1^u = 0.2$) to 11.3% ($h_1^u = 0.8$). Regarding the remanufacturing speed r_1, the analysis is similar to the cases of h_1^u: the cost of the DLSR is very sensitive and increases as the value of r_1 increases, as we mentioned at the beginning of this subsection for the analysis of the results presented in Table 1. In addition,

Table 2. Comparison of the average costs of the DLSR and DLSP optimal solutions for the case $K_1^r = 200$.

			DLSR	DLSP	Gap
$K_1^r = 200$	R_{1t}	**50**	11217.9	10789.1	4.0%
		70	10778.4	10877.5	-0.9%
		100	9346.2	10836.6	-13.8%
	h_1^u	**0.2**	8736.0	10831.8	-19.3%
		0.5	10520.5	10816.1	-2.7%
		0.8	12086.0	10855.3	11.3%
	r_1	**200**	9415.7	10881.8	-13.5%
		300	10527.7	10810.3	-2.6%
		400	11399.1	10811.1	5.4%

we observe that the costs are significantly favorable for the DLSR in the case in which the production and remanufacturing speed are the same ($p_1 = r_1 = 200$).

Table 3. Comparison of the average costs of the DLSR and DLSP optimal solutions for the case $h_1^u = 0.2$.

			DLSR	DLSP	Gap
$h_1^u = 0.2$	R_{1t}	**50**	10938.7	10812.1	1.2%
		70	10636.5	10856.8	-2.0%
		100	10226.5	10744.7	-4.8%
	K_1^r	**200**	8736.0	10831.8	-19.3%
		500	9862.4	10808.2	-8.8%
		2000	13203.3	10773.7	22.6%
	r_1	**200**	9881.1	10833.5	-8.8%
		300	10740.5	10801.3	-0.6%
		400	11180.1	10778.9	3.7%

Table 3 shows the results for the instances with $h_1^u = 0.2$. The meaning of the columns is the same as in Table 2. From Table 3 we can note that there are more instances in which the costs of the DLSR is lower than the costs of the DLSP (negative values in column "Gap"). The effect observed for the returns cases R_{1t} is similar to that seen in Table 2, but less marked: as returns amounts increase, the cost of the DLSR decreases. A high sensitivity for the costs of the DLSR optimal solutions is observed against different values of K_1^r, with a percentage gap from -19.3% for $K_1^r = 200$ to 22.6% for $K_1^r = 2000$. For the cases of the remanufacturing speed (r_1), the results are also similar for that observed in Table 2, but, once again, not so marked.

3.3 Analysis of results for large instances

We present in this subsection the results of the experiments carried out to evaluate the computational effort required to solve the problems DLSR and DLSP.

In Table 4 we present the runtimes in seconds for each problem, along with the number of times that the time limit of 1800 seconds, established to CPLEX, is attained. In Figure 1 we show the CPU times required by CPLEX for solving the problems for the different values of T under consideration, represented on a logarithmic scale. As it can be seen in Table 4 and Figure 1, DLSR is considerably more computationally expensive than DLSP. While the CPU times for the DLSP are around 1 second (even for the larger case of $T = 132$), in the case of the DLSR, they grow suddenly (more than 500 seconds for $T = 132$). This is evidenced by the number of times that the time limit of execution is reached by CPLEX for the DLSR, which begins to increase in larger instances. On the other hand, for the DLSP the time limit is never attained.

Table 4. Average runtimes (in seconds) and number of times that the execution time limit is reached by CPLEX to solve the problems DLSR and DLSP for the different values of T considered.

	DLSR		**DLSP**	
T	**Runtime**	**#Tim.lim.**	**Runtime**	**#Tim.lim.**
22	0.07	0	0.006	0
44	0.53	0	0.10	0
66	9.02	0	0.26	0
88	134.03	4	0.82	0
110	362.44	13	1.11	0
132	513.67	19	1.34	0

Finally, we note that the cost gaps for the large instances show, on average, the same behaviour as that observed for the 810 instances with $T = 22$ periods, that is, around a 15% increase for the DLSR compared to the DLSP.

4 Conclusions

In this paper we have tackled an extension of the discrete lot-sizing and scheduling problem in which the demand requirements of products can be also satisfied by remanufacturing used products returned to the origin. We refer to this problem as the discrete lot-sizing and scheduling problem with remanufacturing (DLSR). Remanufacturing can be considered as a key element of the Circular Economy, a paradigm that has emerged to counteract the negative effect on the environment of the traditional linear production of produce, use and dispose.

We provide a MILP formulation for the problem and analyze the results of a numerical experimentation carried out for the case of a single product, with the aim to compare the efficiency in both costs and solving time of the DLSR against the DLSP (the traditional problem without returns). From the numerical experiments conducted, we conclude that the problem extension with recovery options can offer economic benefits in the case of low-cost returns and, to a lesser extent, for those cases in which the number of returns is relatively high compared

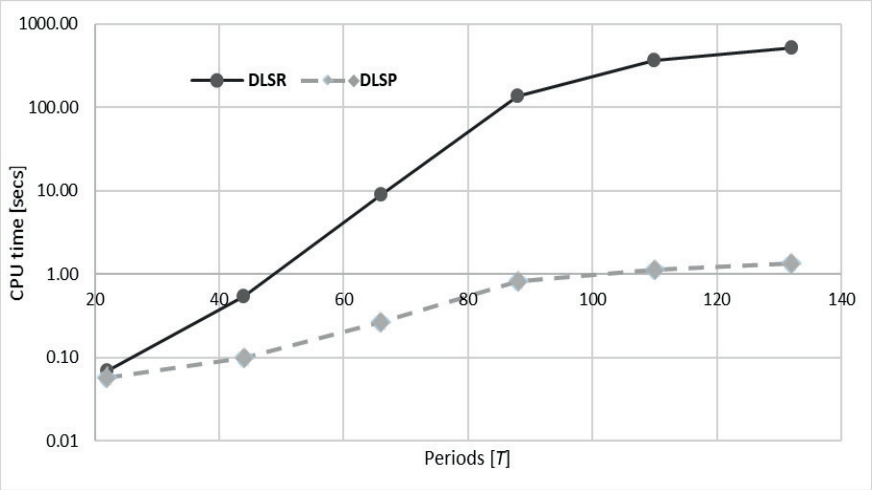

Fig. 1. CPU times in average required by CPLEX to solve the problems DLSR and DLSP for the different values of T. The CPU time is expressed in logarithmic scale in seconds.

to the demand requirements. In addition, we note that similar production and remanufacturing speeds appear to be a more favorable configuration, even in those cases with large returns. In terms of solving times, we show that the DLSR is much harder to solve than the DLSP, in particular, as the size of the instances increases. Thus, we conjecture that the DLSR belongs to the complexity class of NP-hard problems.

Taking into account the results of the numerical experimentation summarized above, future research on DLSR should involve the development of efficient and effective solving procedures for the problem, possibly extending those suggested for the DLSP or ELSR. Another interesting topic to address is the analysis of the order of complexity of the problem. This analysis should involve not only the general case, but also particular cases such as the case of a single product as in [24] for the DLSP, or the case of sufficient returns at the first period as in [15] and [16] for ELSR. It would be also interesting to study the DLSR with more than one machine or processing line. In particular, the case in which production and remanufacturing are allowed in the same period. Considering the environmental side of the problem, it would be interesting to investigate the returns usage rate in the optimal or high quality solutions. Also including more realistic assumptions, such as the non-uniform condition of the returns (heterogeneous quality), may be an interesting extension to consider for the problem tackled here.

Planificación de minutas alimentarias para el casino central de una Universidad Pública de Chile: Un enfoque para la reducción de la huella de carbono

Javiera García-Leal[1], Andrea Teresa Espinoza Pérez[1], and Oscar C. Vásquez[1]

Department of Industrial Engineering, Universidad de Santiago de Chile, Santiago 9170124, Chile,
javiera.garcia.l@usach.cl,andrea.espinozap@usach.cl,oscar.vasquez@usach.cl,

Abstract. El calentamiento global ha tenido impactos negativos en la calidad de vida, la eficiencia de diferentes sectores productivos y el medioambiente. Los principales responsables de este calentamiento global son los gases de efecto invernadero (GEIs), en particular el diéoxido de carbono (CO_2). Por otra lado, la malnutrición es un tema complejo a nivel mundial, alcanzando alrededor del 60% de la población. Este trabajo aborda ambos problemas mediante el planteamiento de un modelo matemático para planificar las minutas alimentarias de un casino de una Universidad Pública de Chile, satisfaciendo requerimientos de calorías, cantidad de raciones diarias y de diversidad de preparaciones; minimizando la generación de dióxido de carbono equivalente (CO_2 eq). Los resultados muestran que una minuta generada por el modelo propuesto permite una disminución de un 96,85% en las emisiones generadas en comparación con aquellas planificadas habitualmente para un periodo base de 25 días. Se concluye que este modelo podría ayudar a generar minutas diarias alimentariamente saludables y ecológicamente amigables.

Keywords: Planificación, Minuta, Huella de Carbono, Calorías, Modelo de optimización

1 Introducción

En la actualidad, los efectos del calentamiento global se han visto reflejados en la escasez hídrica [11], alteraciones en el ciclo hidrológico, derretimiento de glaciares [8], disminución de la producción agrícola y la calidad de los cultivos [5], disminución de la biodiversidad de ecosistemas marinos [10], impactos negativos en la salud [9], entre muchos otros. Los principales responsables de este calentamiento global son los gases de efecto invernadero (GEIs) en particular el dióxido de carbono (CO_2), GEI de larga duración proveniente de actividades humanas [13].

Por otra lado, la malnutrición es un tema complejo a nivel mundial. En el año 2016, un 39% de las personas de 18 años o más tenía sobrepeso y un 13%

sufría de obesidad [6]. En el otro extremo, se encuentra la carencia en la ingesta de energía y/o nutrientes, representada por el 10,8% de la población mundial en el año 2017 [12]. A todo lo anterior, se suma que más de dos mil millones de personas del mundo no consumen los micronutrientes necesarios, es decir, padecen de "hambre oculta" [7].

Nuestra Contribución: Este trabajo aborda ambos problemas: satisfacer los requerimientos alimenticios y minimizar la generación de GEIs. Específicamente, este trabajo propone un modelo matemático que permita planificar las minutas alimentarias para el casino central de una Universidad Pública de Chile, que satisfaga los requerimientos de calorías, cantidad de raciones diarias y de diversidad de las preparaciones; minimizando la generación de dióxido de carbono equivalente (CO_2 eq).

2 Descripción del problema

En la Universidad Pública bajo estudio, una entidad especializada es la que diariamente planifica las minutas alimentarias que ofrece el casino central a toda la comunidad. Formalmente, la entidad planifica la minuta para un conjunto de días hábiles $\mathcal{D}$ que componen 5 semanas, donde $\mathcal{D}_b$ denotan el conjunto de los días de b-esima semana ($b = 1, \ldots$), i.e $\mathcal{D} = \bigcup_{b=1}^{5} \mathcal{D}_b$.

Esta entidad especializada considera un conjunto de preparaciones $\mathcal{A}$, el cual es definido por la unión de tres subconjuntos disjuntos definidos por un conjunto platos de fondo $\mathcal{A}_I$, un conjunto de postres $\mathcal{A}_J$ y un conjunto de entrada $\mathcal{A}_K$. Una *minuta* para un dia $d \in \mathcal{D}$ corresponde a una tripleta de tres preparaciones: plato de fondo $i \in \mathcal{A}_I$, postre $j \in \mathcal{A}_J$ y entrada $k \in \mathcal{A}_K$. Sea $\mathcal{W}$ el conjunto total de alimentos considerados por las preparaciones. Cada preparación $a \in \mathcal{A}$ es elaborada a partir del conjunto de alimentos, donde la cantidad de cada alimento $w \in \mathcal{W}$ es denotado por $F_{w,a}$. Asimismo, cada preparación $a \in \mathcal{A}$ posee C_a calorías y para cada día $d \in \mathcal{D}$, se debe satisfacer un rango de calorías entre $\underline{Cal}$ y $\overline{Cal}$ junto a una cantidad de raciones del día N_d.

Por política de diversidad de las preparaciones, los platos de fondo y las entradas no pueden repetirse durante el periodo de planificación, mientras que los postres no pueden repetirse en la semana.

Sea E_w la emisión de CO_2 eq por la producción del alimento $w \in \mathcal{W}$. El problema abordado en este artículo es planificar las minutas para los días hábiles, seleccionando un subconjunto de preparaciones, que minimice la cantidad total de emisión de CO_2 eq provenientes de los alimentos utilizados por las preparaciones seleccionadas, respetando los rangos de calorias, cantidad de alimentos y diversidad de preparaciones.

3 Modelo Matemático

Sea $x_{a,d}$ una variable binaria que toma el valor 1 si la preparación $a \in \mathcal{A}$ se entrega el día $d \in \mathcal{D}$, cero en otro caso.

3.1 Función Objetivo

$$[\text{MIN}] \sum_{d} \sum_{w} \sum_{a} F_{w,a} \cdot E_w \cdot x_{a,d} \cdot N_d \tag{1}$$

3.2 Restricciones

$$\sum_{d} x_{i,d} \leq 1 \quad \forall \quad i \in \mathcal{A}_I \tag{2}$$

$$\sum_{d} x_{k,d} \leq 1 \quad \forall \quad k \in \mathcal{A}_K \tag{3}$$

$$\sum_{d \in \mathcal{D}_b} x_{a,d} \leq 1 \quad \forall a \in \mathcal{A}_J; b = 1,2,3,4,5 \tag{4}$$

$$\underline{Cal} \leq \sum_{a} C_a \cdot x_{a,d} \leq \overline{Cal} \quad \forall d \in \mathcal{D} \tag{5}$$

$$\sum_{a \in \mathcal{A}_s} x_{a,d} = 1 \quad \forall s = I, J, K; d \in \mathcal{D} \tag{6}$$

La expresion (1) describe la función objetivo del modelo y cuantifica el total de emisiones de CO_2 de los alimentos asociados a las minutas. El conjunto de restricción (2) y (3) indica que las preparaciones de plato de fondo y entrada no pueden ser repetidas durante el periodo de estudio, de igual manera, el conjunto de restricciones (4) limita la frecuencia de repetición de los postres a una semana. El conjunto de ecuaciones (5) restringe la cantidad de calorías de la minuta diaria. El conjunto de restricciones (6) condiciona la planificación diaria, de modo que sólo se puede elegir una preparación de plato de fondo, postre y entrada cada día.

Los datos obtenidos para la definición de parámetros desde la unidad especilizada fueron las cantidades de raciones diarias, las calorias máximas $\overline{Cal} = 690$ y calorias mínimas $\underline{Cal} = 450$, además de las preparaciones descritas por $|\mathcal{A}_I|$=76 platos de fondo, $|\mathcal{A}_J|$=31 postres y $|\mathcal{A}_K|$=44 entradas, las cuales se combinan para crear la minuta diaria. Las emisiones de CO_2 eq son obtenidas de estudios de Análisis de Ciclo de Vida (LCA) de la literatura ([4], [1], [2]) y de la calculadora ecológica chilena EcoBase [3].El modelo matemático fue implementado en GAMS 2.0.54.3 utilizando CPLEX 12 como solver, en un ordenador con un procesador Intel(R) Core(TM) i5-9300H CPU, 2.40GHz y una memoria RAM de 8 GB.

4 Resultados y Conclusiones

Los resultados obtenidos por el modelo entregan una planificación de minutas diarias para el periodo de estudio cuya cantidad total de CO_2 eq alcanza los 2.212,482 kg. Este valor corresponde a una disminución de 96,85% respecto a la minuta desarrollada por la unidad especializada de la Universidad Pública durante el mismo periodo. La Figura 1 muestra el CO_2 eq emitido durante cada día del período de estudio, generada por minuta diaria generada por al unidad especializada de la Universidad Pública y minuta diaria generada por el modelo de opimizaci ón. Las líneas segmentadas de la Figura 1 indican la emisión diaria promedio de cada minuta, siendo representada la minuta real con color azul, mientras que la minuta planificada/optimizada, en color naranjo.

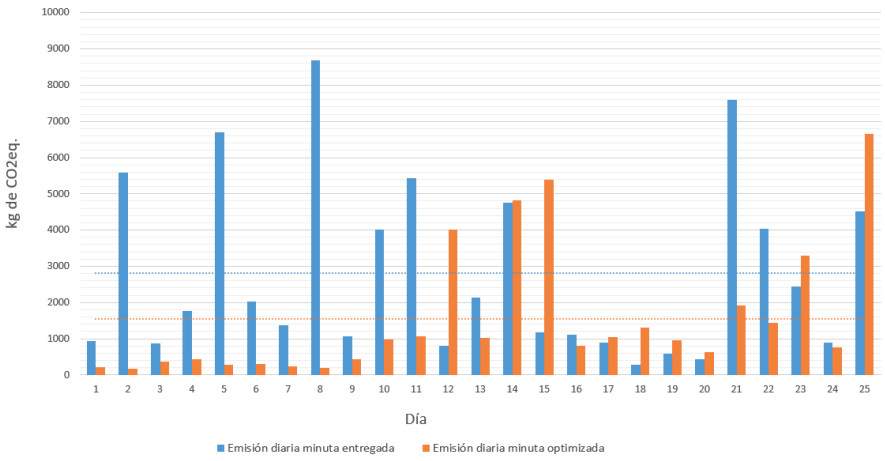

Fig. 1: Emisiones diarias de CO2 eq.

Se concluye que este modelo podría ayudar a generar minutas diarias alimentariamente saludables y ecológicamente amigables. Para trabajos futuros, se recomienda la incorporación de otros factores como los requerimientos de nutrientes y la posible implementación del modelo dentro de una herramienta computacional que sea de fácil uso para el tomador de decisiones.

Abstract. The theme Industry 4.0 is a topic that interest is rising in several areas, as it deals with a revolution in the form of production through the introduction of disruptive technologies, which completely changes traditional processes. In parallel, there is great pressure from communities and governments for sustainable development from a social and environmental point of view, this makes companies look for technologies capable of contributing to a sustainable development policy of the organization. The present work aims to analyze articles that aim to investigate the means of investments in clean technologies and environmental innovations, such as estimates of return on investments and their barriers. Through the methodology of a systematic literature review, a bibliographic portfolio was composed of scientific articles. To make research feasible, limited taxes were considered, considering only articles published in the English language, between the years 2000 to 2019 and available in the Web of Science, Scopus, and Science Direct databases.

Keywords: investments, digital technologies, innovation, sustainability, systematic literature review.

1 Introduction

The era of industry 4.0 intrinsically related to advanced production systems, with real-time communication with each other, and also to the possibilities of various data-based analyzes and predictions [1], as well as digital transformation technologies a significant change in the production process [2], brings up the concern about the scarcity of resources pollution, water and air pollution [3], among other forms of environmental degradation. Thus, the current manufacturing models of companies when revealing such

negative social and environmental impacts, stimulated an awakening of awareness on the theme by companies [4].

Ji et al. [5] stated in their study that to contribute to environmental conservation, companies should develop a policy of investing in cleaner technologies, as well as developing better energy efficiency, and creating a sustainable culture. The empirical data from the study by Drohomeretsk et al. [6] has as one of the highlights of their work the practical implication that the use of technologies in equipment can contribute positively to the environmental and economic performance of a company's operations. Machado et al. [7] state that sustainable operations management can be a set of capacities and processes that support business models based on sustainability that have better environmental, social and economic practices as goals. For Böhringer et al. [8] investments in this sense aim to reduce environmental damage, as well as Klassen and Vanchon [9], reiterate that operational investments aim to reduce pollutants in the natural environment. However, these investments are expensive, with longer and riskier payback periods, resulting in limitations for obtaining investments in environmental innovation [10].

Since technologies are means for the sustainable development of corporations, capable of positively impacting the productive processes of companies, often allowing productions to operate in an adaptable and flexible way, or even to have systems for managing waste, processes for reducing or eliminating waste from production methods, among others, but on the other hand, companies have limited resources for investments, or even resist investments in technologies aimed at sustainable development, as they understand that this type of investment may have an uncertain or long-term return, or even ignore the possible benefits that such an investment can provide to the company's operations. With this, the present work aims to investigate through systematic literature review and content analysis, how investments are made in environmental technologies and innovations and what barriers organizations face in this context in the era of digital transformation.

2 Method

The research was carried out using the Proknow-C method (Knowledge Development Process - Constructivist) [11] to compose a portfolio of scientific articles that addressed aspects of the investments, technologies, and sustainability axes.

The Proknow-C method consists of executing several pre-defined steps, as outlined in figure 1, aiming to compose a portfolio with articles of scientific relevance and aligned with the research theme [11].

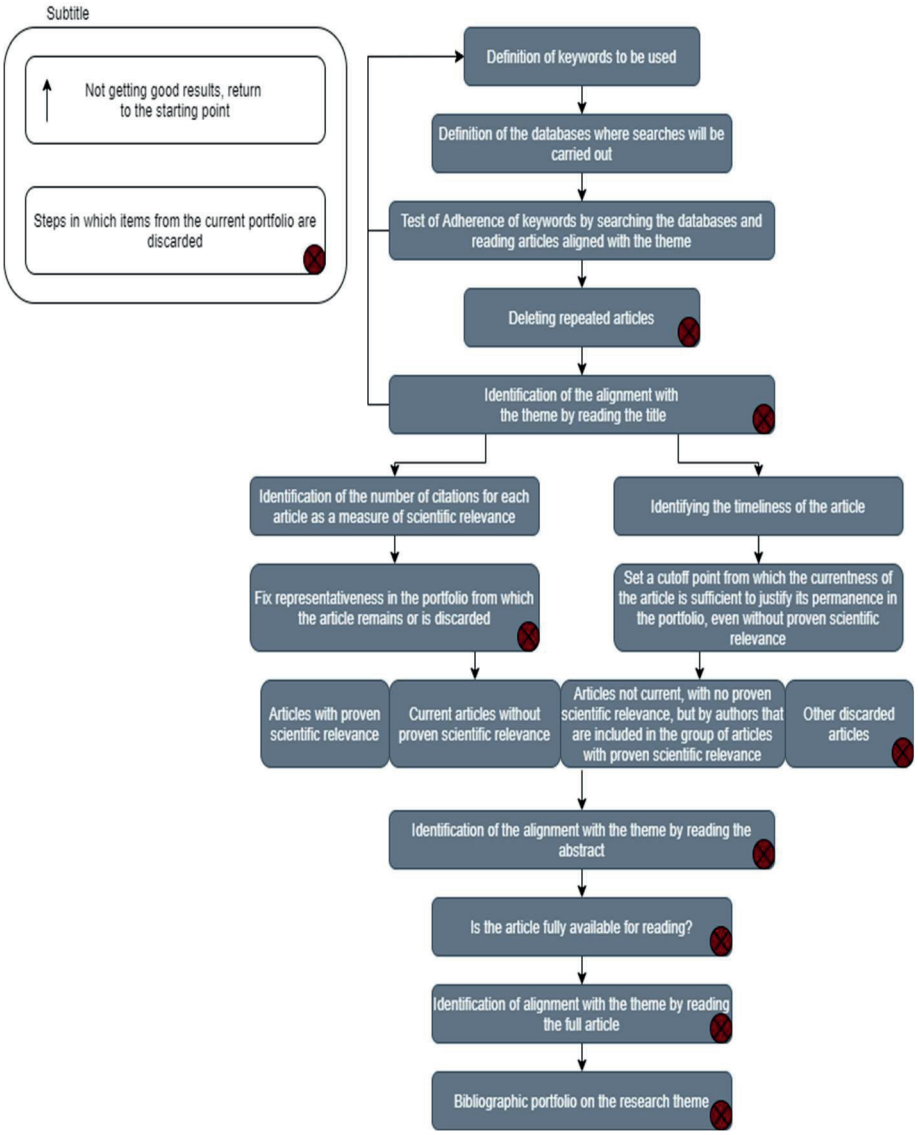

Fig.1 Proknow-C method developed by Ensslin et al. 2010

The first stage of Proknow-C aims to define the research axis and the keywords used in the database search systems, to locate scientific articles by the topic addressed.

The researcher must define the best database to search for articles, if it is not possible to state the best database, the search for scientific articles should be carried out in several databases, since depending on the research area, a database may have greater representation concerning the other, so that if the survey is carried out in several bases,

increase the possibility of locating a larger number of studies that address the research topic.

In this phase, the search expressions in the databases should be imputed, these keywords can be entered individually or combined, and the researcher must also determine limitations regarding the language, period, publication channels and type of bibliographic material, thus allowing research becomes possible.

In the definition of keywords, the researcher must assess whether they are returning articles that are related to the research axis. Therefore, it is suggested that the researcher fully analyze at least two articles, which allows elucidating if the expressions used in the search systems are reflecting articles related to the research.

After this stage of "hunting" scientific articles related to the topic, the researcher will have a raw portfolio, with articles that may or may not be related to the research proposal. Then other filtering processes must be employed to discard articles that do not belong to the scope of the research.

In subsequent steps should be made more filters, which use analysis starting from the titles, abstracts, scientific relevance. This allows obtaining a higher proportion of relevant articles, which have a closer relationship with the research, which, in turn, leads to the provision of a more refined, yet comprehensive portfolio to the point of providing sufficient and essential information to the investigator.

Bearing in mind that the researcher has articles from several databases, there is a possibility that repeated articles have been returned as a result, since a given article may be in multiple bases, so filtering is also necessary for excluding repeated articles.

The next step consists of checking the scientific relevance of the selected articles, in which the researcher should look for the number of times that the articles were cited in other studies. To perform this verification, the tool “Google Scholar” is suggested, in which the title of the article is inserted in the search field of the tool, immediately following the number of times that the researched article was cited, which allows the researcher to evaluate, simply and practically, if the article obtained has proven scientific relevance. However, as suggested by Ensslin et al. (2010) [11], each situation should be assessed individually, given that each research topic has its characteristics, thus being able to present inconsistency both in the number of articles and in the number of citations. Still in this stage in question, the researcher can establish a cut-off number, where he classifies which articles are scientifically recognized and which do not yet have them, and which therefore require further analysis, to decide whether or not to compose the database. Dice. The suggestion of the authors of the method is that the representativeness of scientific articles with confirmed recognition is around 85% concerning the article bank.

In the final phase, the articles established as scientifically significant, are validated by the researcher through reading and analyzing the abstract, which will also allow determining whether the article is in line with the investigated theme, and will remain in the portfolio, or not, and in this case, must then be discarded.

3 Results

From the Systematic Review of Literature performed according to the method described - Proknow-C - the following results were obtained, followed by a brief analysis:

3.1 Portfolio

According to table 1, the keywords were inserted in the Web of Science, Scopus, and Science Direct databases. To limit the search, the searches were restricted to the English language, between the years 2000 to 2019.

Table 1. - Gross Bibliographic Portfolio

Keywords	Data Bases			Total
	Web of Science	Scopus	Science Direct	
(Financing or Investment or feasibility) and (sustainable or sustainability or environmental innovation or carbon emissions or low pollution or prevention control) and (technology or industrial revolution or industry 4.0 or eco-innovation or disruptive innovation or technology)	447	478	999	1924

In the next step, to confirm whether the search terms were in agreement with the investigated subject, 4 related articles were read, and thus it was found that the keywords were significantly appropriate (see table 2).

Table 2. - Articles selected to verify agreement with the investigated subject

References corresponding to selected articles

Then duplicate articles were excluded. Subsequently, the titles and abstracts of the articles were observed, and, in the presence of disagreement with the proposed question, discarded. Thus, only articles according to the research axis, which comprised the review portfolio, were maintained.

The final bibliographic portfolio consisted of 25 articles. According to table 3.

3.2 Portfolio description

With bibliometric analyzes it was possible to verify that the year 2017 was the year with the highest index, totaling 6 publications, followed by the years 2018 and 2015 with 5 publications each year, with this it is possible to conclude that the interest in understanding the investment movement in technologies and sustainability has been growing in recent years. For Boons and Lüdeke-Freund [12], research on sustainable innovations has been expanding and thus leads us to an understanding that the main way to obtain sustainable societies is through new technologies and social practices.

Just over 32% of the publications in the bibliographic portfolio were made in the Journal of Cleaner Production, which, as stated on the Elsevier website [13], is a journal focused on cleaner, environmental and sustainable research and production practices.

When assessing the number of citations by authors, authors were identified who obtained the scientific relevance of their work, already proven, such as the author's Boons, and Lüdeke-Freund [12] who had their work Business models for sustainable innovation: State-of-the-art and steps towards a research agenda published in the Journal of Cleaner Production cited 1,383 times according to data obtained from the website googles scholar.

3.3 Content analysis

From the bibliographic portfolio, a content analysis was carried out to identify the relationships between the investments, technologies, and sustainability axes and to identify the gaps in studies.

The content analysis consists of a set of methodological techniques that are applied to diversified content so that models can be structured based on the information extracted [14].

Following the methodology of Bardin [14], from the pre-analysis of the material, clippings of the texts were carried out to carry out the categorization in comparable units.

In Fig. 2 it is possible to check the categories and codes created from the bibliographic portfolio and how the articles were classified, presenting an overview of the types of existing investments, how the investments are evaluated and what are the existing barriers regarding investments in technologies and sustainable development.

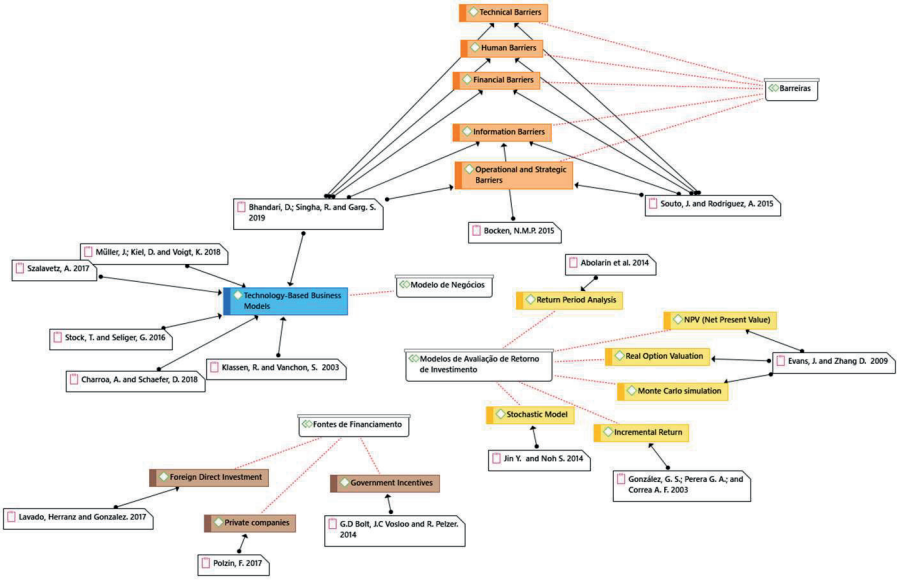

Fig. 2. Categorization and Coding Content Analysis

Day after day, innovations focused on sustainability are gaining more and more attention. As shown in Fig. 3, financing can be made by the public, private companies, and from internal and external sources. According to Polzinz [15], for companies to break through a complex barrier of environmental innovation, it ends up with the help of public institutions through the development of technologies in their institutes and receives contributions from private companies through donations and subsidies.

The 12I is a tax incentive granted by the Republic of South Africa that aims to promote new industrial projects as well as assist in the modernization of existing projects through innovative processes and the acquisition of clean technologies [16].

In the context of small and medium-sized companies, there is a great difficulty in the development of projects and research, this is because these companies usually have limited resources [17], in this sense, according to studies by Melane-Lavado; Herranz; Gonzalez [18], foreign direct financing is a financing stabilizer, because,

when the company does not have access to internal resources, it may have access to external private or public resources.

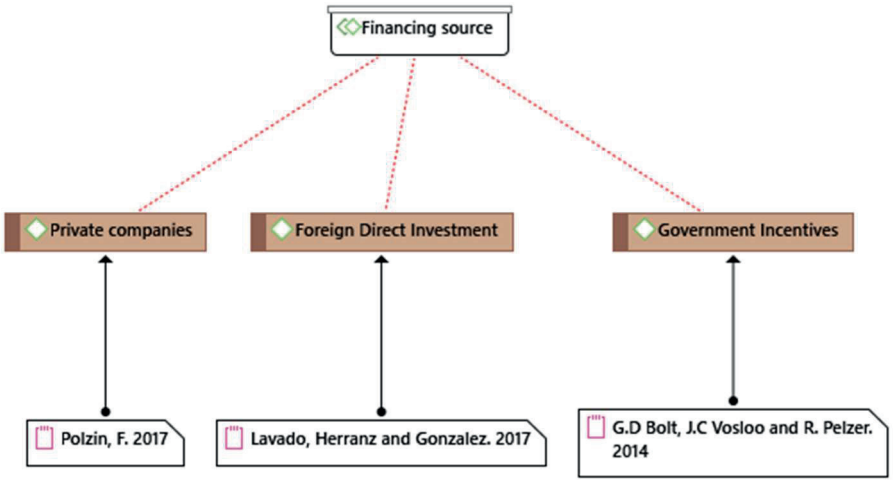

Fig. 3. Financing source.

In the presented business models, it was possible to observe models based on technologies, such as cloud computing [1]environmental technologies in the supply chain [9], clean technologies [19], industry technologies 4.0 [20-21]. For Bhandari; Singh; Garg [19], in addition to being efficient, new technologies develop sustainability from resource consumption, so also says Szalavetz [22] arguing that with the use of advanced manufacturing technologies it is possible to achieve operational excellence, improve the cost-benefit ratio and have a beneficial impact on environmental performance.

González; Perera; Correa [4] state that for decision making on investments related to production, it is necessary to analyze the environmental consequences, however, the traditional financial analyzes do not include environmental impacts, and from this problem, the authors argue that the method of incremental feedback could correct this problem by considering environmental impacts and social benefits in the assessment. Techniques such as ROI (Return on Investment) or the break-even point that are often used, may not provide reliable information [5].

In the context of the automotive industry, considered a highly competitive market and with a growing demand for eco-efficient and sustainable cars, Evans and Zhang [23] state in their study that the real option assessment helps managers understand the administrative and operational flexibility, so that investment-related decision making takes into account, in addition to market conditions, the volatility of the project's value.

The models for evaluating the return on investments considered in the bibliographic portfolio are presented as shown in figure 4.

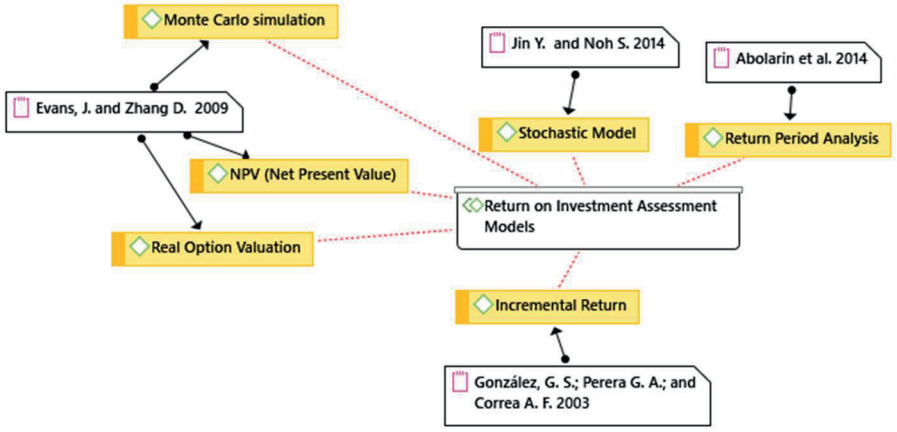

Fig. 4. Investment Evaluation Models.

Since the 1980s, financial barriers have been identified as the main barriers to technological development [24]. Funds and financial institutions that encourage the development of clean technologies are lacking (BHANDARI; SINGHA; GARG, 2019) [19]. Bocken, [25] states that one of the existing barriers to investing in sustainable technologies is the lack of knowledge on sustainability on the part of investors. For Polzin [15], there is a combination of financial, institutional and transition factors that weaken the development of clean technologies, limited access to external sources of finance, the high cost of innovation and the lack of information about the market are factors that limit environmental innovation (SOUTO; RODRIGUEZ, 2015) [26].

Projects that involve sustainable development have the characteristic of having longer terms of return on investment, thus, the investor ends up losing interest in this type of operation, since it seeks to make investments with quick gains (BOCKEN, 2015) [25]. As shown in Figure 5, it was possible to identify numerous barriers faced by organizations to put financial actions into practice within their operations.

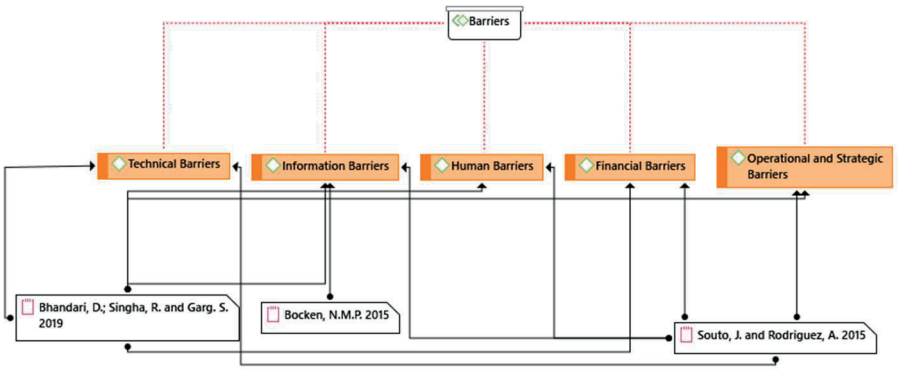

Fig. 5. Barriers to technological innovation in sustainable development.

3.4 Analysis

The development of this research began with the systematic review of the literature, using the Proknow-C method [11]. Based on SLR, a bibliographic portfolio was created, comprising 25 scientific articles related to the areas of investment in cleaner digital transformation and production technologies.

Based on the literature, whether due to legal issues or external pressures, companies are increasingly interested in sustainable development, which ends up having an impact on the academic world, reflecting the interest on the part of researchers to carry out studies on the subject. This trend is perceived in the present study, where the number of publications is increasing year after year.

Many studies are focused on models for evaluating return on investments because investments in environmental innovations and clean technologies are often seen as expensive and long-term investments, which ends up reducing the interest on the part of investors.

Despite the increased interest on the part of organizations in the topic of sustainable development, several authors portray in their studies the barriers to the implementation of sustainable actions in company operations.

A highlight for the financial barrier, that is why 1988 Ashford et al. [24] they already stated that financial barriers are one of the most important groups for the execution of technological changes. In agreement with the statement by Ashford et al. [24], Polzin [15] reiterates that financial and economic barriers are restrictive to innovation in cleaner technologies and technology in general.

4 Conclusion

At a time when technological development is advancing rapidly, with the existence of smart, connected industries and a scenario of increasingly scarce environmental resources, there is an increasing demand from customers and investors for less impacting actions for the environment- environment,

To understand the existing relationships between investments in technologies and sustainability, the present study sought to compose a bibliographic portfolio with articles published from the 2000s until 2019 that dealt with investments in technologies and could make companies sustainable from the point of view. environmental and social views. Therefore, 25 articles were considered in the portfolio, including the article by Boons and Lüdeke-Freund [12] with 1383 citations who have contributed to the development of the literature by demonstrating that sustainable business models and innovations are interrelated in current literature, as well as proposing a normative requirement that business models for innovation should consider. Another point to highlight is the number of publications in the Journal of Cleaner Production, which received 9 publications out of a total of 25 articles. With the content analysis method, it was possible to identify some relationships between the articles, among them the financing of technological innovations with private resources, foreign capital, and public resources through tax exemptions as well as the support of public institutes for the development of technologies.

About investment return valuation models, traditional valuation models and models that consider environmental and social impacts have been identified, such as example of incremental return González, Perera and Correa [4]. In general, the authors argue that traditional validation models are not reliable when it comes to obtaining information on environmental and social results, for them, the models lack real information and that the operations of organizations are reliable.

Finally, several types of barriers to sustainable technological development are pointed out in research, including the barrier of knowledge, information, operational and strategic, technical, human and financial, the latter highlighted, as this is where organizations face the greatest resistance, this why both private and public institutions have low confidence in the return on investments, or why the return periods are long, thus, these institutions choose to make short and medium-term investments.

Finally, this work provided support for an overview of investments in technologies and innovations in the field of sustainability.

Abstract. A mathematical model for the pulp and paper supply chain (P&PSC) network design is presented in this work, where the integration of bioethanol production is evaluated. The optimization model is used to analyze the impact of three cost reduction strategies: economies of scale, transport, and dynamic capacity. The problem is formulated as a generalized disjunctive programming (GDP) model and reformulated as mixed integer linear programming (MILP) one. It is implemented in GAMS and its feasibility has been tested using data from a real case study from Argentina.

Keywords: Pulp and Paper Industry, Bioethanol Production, Supply Chain Integration, Cost Optimization

1 Introduction

Nowadays, the pulp and paper industry is not competitive. The integration of a biorefinery into an existing pulp mill has been determined as a potential pathway for a long-term sustainable growth of pulp and paper industry. Among all the existing possibilities to incorporate biorefineries into P&PSC, this paper deals with the problem of integration of bioethanol production into them [1]. From an Argentinian perspective, the inclusion of biorefineries within the traditional forest industry is of particular interest. In this sense, the problem is presented as an optimization one, formulated by means of a GDP model, which was adapted from a previous work [2]. This contribution analyzes the impact of two cost reduction strategies: economies of scale and dynamic capacity. The aim of this study is to examine the impact of these cost strategies by means of a single comprehensive optimization model.

2 Problem definition and case study

The P&PSC considered in this work involves three echelons: harvesting sites, conversion facilities and consumer regions. Fig. 1 shows the general structure of the

proposed P&PSC and the possible relations among facilities. The P&PSC includes a set of nodes for distributed facilities (nodes *j* and nodes *k* for potential location of pulp mills and paper factory, respectively); and the set of nodes *l* for the integrated ones where different types of plants can be installed.

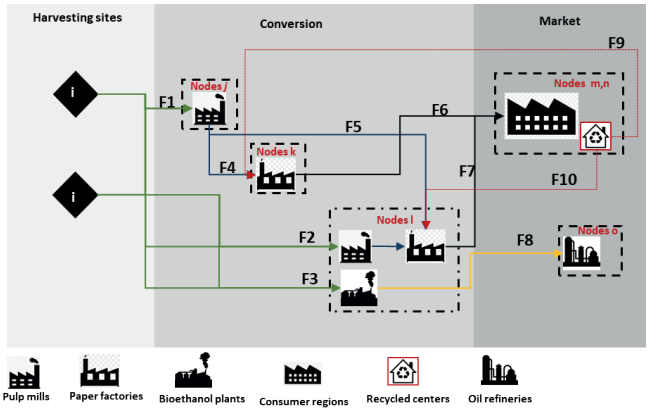

Fig. 1. Generic view on the considered P&PSC, material flow between nodes are represented by solid arrows (direct flow) and dashed arrows (reverse flow).

As in the previous contribution presented by [2], the base scenario (S_0) determines: area of land to harvest; the number, technology, location, and the dynamic capacity profiles of all facilities; and the transportation flows along all P&PSC nodes. In addition, the two cost reduction strategies proposed in this work (see Table 1), involve several modifications both in the mathematical model, and parameters, as well as in the objective function, resulting in optimal design alternatives for the supply chain.

The case study assumes five available harvest areas with two types of raw materials. A total of 14 possible locations for production facilities are assumed. For each plant type, a set of 7 capacities are considered. Five paper consumer's regions are selected, each of them is assigned a recycled paper center. In addition, four largest oil refineries in the country are defined as consumers of bioethanol. Piecewise linearization of transportation cost function through trucks is assumed, costs vary according to the material transported and distance.

Model parameters and some assumptions are determined considering values from the Argentinian forest industry, except the ones related to ethanol production which are taken from the literature. Alternative scenarios (see Table 1), were run to isolate the role of different cost reduction strategies and examine the impact of P&PSC design.

Table 1. Cost reduction strategies

Scenario	Description
S_1	The maximum capacity level is reduced in 27%, to explore the impact of limiting economies of scale.
S_2	Fixed global capacity facility approach is assumed. This scenario is used to explore the impact of introducing dynamic capacity approach.

3 Results and Discussion

The models comprise 42564 constraints, 3560 integer and 19561 positive variables. All instances were implemented in GAMS 24.7.4 with a 2.5 GHz Intel Core i5 processor and solved using CPLEX 12.6.3.0 and took between 50 and 107 CPU seconds to obtain a gap of 0%. Fig. 2 shows the cost breakdown for all scenarios. Table 2 presents of the number and type of plants and the capacity profile for each scenario considered.

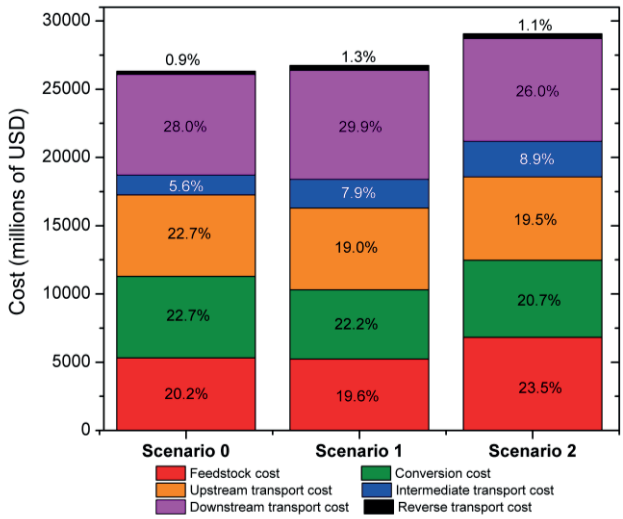

Fig. 2. Optimal cost of P&PSC design for each considered scenarios

Table 2. Number, type of plants and the capacity profile for each scenario considered

			General capacity profile				
Scenario	**Type of facility**	**# of facilities**	**1**	**2**	**3**	**4**	**5**
S_0	Bioethanol	2	20%	20%	39%	39%	100%
	Paper factory	7	41%	48%	48%	56%	100%
	Pulp mill	9	49%	56%	59%	76%	100%
S_1	Bioethanol	1	20%	20%	20%	20%	100%
	Paper factory	8	48%	53%	60%	74%	100%
	Pulp mill	9	43%	58%	66%	87%	100%

	Bioethanol	5	-	-	-	-	-
S_2	Paper factory	10	-	-	-	-	-
	Pulp mill	9	-	-	-	-	-

Large scale versus small scale. Scenario 1 shows a rise in transport cost, the total P&PSC cost is 2% greater than in the baseline case. The increment in the cost of transportation is mainly caused by rising pulp transportation cost and higher recycled paper transportation cost. In addition, similar dynamics of base scenarios are visible in the scenario 1: the benefits of the integration of several forest industries in the same node are used as well as the dominance of economies of scale by selecting large capacity levels. However, unlike the baseline scenario, only one bioethanol facility is located. Moreover, one more paper plant is located in the west of the country, while cellulosic pulp plants are located mainly in the northwest of the country, which explains the increase in the costs of cellulosic pulp transportation (intermediate transport cost) and a greater use and transportation of recycled paper (reverse transport cost).

Fixed versus dynamic capacity allocation. The impact of fixed capacity allocation approach was tested in Scenario 2, which shows a worst supply chain performance in terms of costs, i.e., it is 10% greater than in the baseline case. The best solution suggests the installation of most industries in the first and second year of the planning horizon. Scenario 2 shows a similar dominance of economies of scale but it is characterized by higher overall investment costs (+68%) due to the opening of 6 more facilities compared to the base scenario. Intermediate transport cost for this scenario is 78% higher than the Base scenario for a similar biofuel production level.

4 Conclusions

The proposed model was applied to determine the optimal design of P&PSC considering the bioethanol production. The model involved complex mathematical modeling tasks such as: location and capacity at each node of P&PSC, material flows and interactions among them. In addition, this study evaluated the impact of two strategies to reduce the cost of P&PSC in Argentinian context. Computational results show the model's capability as a decision-making tool for P&PSC design problem. The analysis will be expanded in the future by including the possibility to use harvest residues and facilities byproducts as feedstock as well as considering other industries such as sawmills, medium-density fiberboard and pellets plants among others.

Resumen. La investigación en temas relacionados con las prácticas de la calidad en cadenas de suministro es una tendencia creciente en los últimos años. Es de particular interés el estudio del impacto de aquellas sobre el desempeño de las cadenas de suministro. Aunque en la literatura se han desarrollado trabajos con modelos o metodologías de análisis sobre esta temática, los aportes continúan siendo escasos. Por ello, en este trabajo se desarrolla un modelo estructural de la relación entre las prácticas de calidad y el desempeño sostenible de cadenas de suministro. La metodología utilizada se basó en una revisión exhaustiva de trabajos previos para identificar enfoques y variables. En el modelo desarrollado, las prácticas de calidad se representan en cinco variables de entrada: gestión de proveedores, aseguramiento de calidad, gestión del producto, gestión del cliente y administración y gestión.

Palabras clave: Prácticas de calidad, Gestión de cadenas de suministro, Desempeño sostenible.

1 Introducción

El estudio de las prácticas de calidad como un factor de competitividad es una corriente de investigación que amplía el enfoque tradicional de la gestión de cadenas de suministro con respecto a los elementos que tienen impacto en el desempeño global [1] [2]. Según Robinson y Malhotra [3], la gestión de la calidad en cadenas de suministro (*Supply Chain Quality Management – SCQM*) es la coordinación formal e integración de los procesos que involucran a todos los socios en la cadena de suministro para medir, analizar y mejorar continuamente productos, servicios y procesos para crear valor y lograr la satisfacción de los clientes. Para Foster [4], SCQM es un enfoque del desempeño basado en sistemas de mejora que aprovechan las oportunidades creadas por enlaces ascendentes y descendentes con proveedores y clientes.

Por otra parte, y considerando los requerimientos actuales de la medición del desempeño de las organizaciones y sus cadenas de suministro integrando los tres pilares de la sostenibilidad (ambiental, social y financiero) [5], es necesario especificar aún más el

estudio del impacto de la calidad en el desempeño de las cadenas de suministro. Surge así el concepto de gestión sostenible de la calidad en cadenas de suministro (*Sustainable Supply Chain Quality Management – SSCQM*) [6]. Aunque se han desarrollado trabajos sobre teoría y aplicaciones de SSCQM [7], el estudio del impacto de las prácticas de calidad sobre el desempeño de las cadenas de suministro desde un enfoque de sostenibilidad es un tema relativamente nuevo en el ámbito académico que requiere desarrollos desde distintos enfoques conceptuales y prácticos [8].

En los trabajos previos se destaca el desarrollo de un modelo estructural de la relación entre las prácticas de calidad y el desempeño de la cadena de suministro expresado como el rendimiento en la gestión de inventarios, calidad, finanzas y mercado [9]. Igualmente, se ha probado a través de estudios exploratorios que las prácticas de calidad, tales como liderazgo, planeación estratégica, gestión de proveedores, enfoque al cliente, calidad de datos, gestión de procesos y gestión de recursos humanos, son relevantes para el desempeño de las cadenas de suministro [10].

Se ha utilizado el enfoque del análisis multivariado para probar el impacto de las prácticas de SCQM en el desempeño en calidad del producto final [11]. También, se han desarrollado modelos de ecuaciones estructurales del impacto de las prácticas de SCQM sobre el desempeño organizacional [12] y sobre el desempeño en calidad para el cumplimiento de especificaciones y la satisfacción del cliente [13]. En otros modelos se analiza la interrelación a nivel estratégico y operativo entre Justo a Tiempo, gestión de calidad y gestión de cadenas de suministro y se evidencia su impacto conjunto sobre el desempeño organizacional [14].

En los modelos descritos previamente se analiza y prueba el impacto positivo de las prácticas de calidad sobre el desempeño de las empresas y las cadenas de suministro. Sin embargo, el enfoque de medición del desempeño considerado se centra en aspectos financieros, calidad de producto, gestión de inventarios y satisfacción del cliente. No se evidencia en ellos el desempeño sostenible de las cadenas de suministro como la variable respuesta.

Por ello, en este trabajo se desarrolla un modelo estructural que representa la relación entre las prácticas de calidad y el desempeño sostenible de cadenas de suministro. El modelo propuesto parte del análisis de la literatura de trabajos previos, clasificando los diferentes enfoques respecto a las prácticas de calidad en las cadenas de suministro y se desarrolla una propuesta unificadora con visión integral de la sostenibilidad desde sus tres pilares.

2 Metodología

La metodología utilizada en este trabajo constó de cinco etapas (Fig. 1). En esta sección se describen las tres primeras etapas y, en la siguiente, se muestran los resultados de las etapas cuatro y cinco.

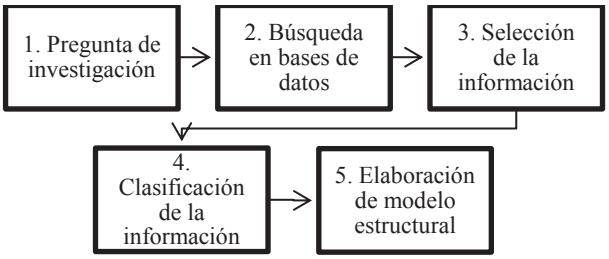

Fig. 1. Etapas de la metodología.

2.1 Pregunta de investigación

El desarrollo del trabajo partió de la formulación de la siguiente pregunta de investigación: ¿Cuáles son las variables que integran un modelo que represente la relación entre las prácticas de calidad y el desempeño sostenible de cadenas de suministro?

2.2 Búsqueda en bases de datos

La búsqueda de información de trabajos previos se realizó en las bases de datos *Emerald*, *Science Direct*, *Scopus* y *Taylor & Francis*, considerando el periodo de tiempo entre los años 2000 y 2020. Se utilizaron las ecuaciones de búsqueda: "*quality practices*" AND "*sustainable supply chain management*", "*quality practices*" AND "*sustainable supply chain*" AND "*performance*", "*quality management*" AND "*supply chain management*" AND "*performance*".

2.3 Selección de la información

La selección de la información (trabajos previos) se llevó a cabo aplicando los siguientes criterios de inclusión: (i) El documento presenta un modelo o una aplicación de prácticas de calidad en cadena de suministro, y (ii) El documento presenta un aporte sobre el desempeño sostenible de cadenas de suministro. Asimismo, se excluyeron los documentos que: (i) Presentaran modelos o aportes sobre gestión de cadenas de suministro sin considerar las prácticas de calidad, y (ii) Presentaran aportes sobre el desempeño de cadenas de suministro sin considerar los tres pilares de la sostenibilidad.

3 Resultados

3.1 Clasificación de la información

Aplicando los criterios de búsqueda en bases de datos y de inclusión y exclusión descritos previamente, se recuperaron un total de 19 trabajos. Estos fueron analizados con el fin de dar respuesta a la pregunta de investigación planteada y los resultados de la clasificación esquemática se muestran en la Tabla 1. La primera columna corresponde a las variables identificadas (prácticas de calidad en cadenas de suministro), la segunda

columna contiene los descriptores de cada una de las variables y en la tercera columna se muestran los autores relacionados.

Tabla 1. Clasificación de prácticas de calidad en cadenas de suministro.

Práctica de calidad	Descriptores	Autores
Gestión de proveedores	- Integración con proveedores - Gestión de relaciones - Desarrollo de proveedores	[9], [10], [11], [12], [13], [14], [15]
Aseguramiento de calidad	- Protocolos de calidad - Estándares - Calidad de datos e información - Cultura de calidad	[9], [10], [12], [13], [14], [16], [17], [18], [19]
Gestión del producto	- Innovación en el producto - Evaluación comparativa - Gestión de procesos - Diseño del producto - Ciclo de vida del producto	[9], [10], [12], [13], [14], [15], [16], [20], [21], [22], [23]
Gestión del cliente	- Enfoque al cliente - Gestión de relaciones - Satisfacción del cliente	[9], [10], [11], [12], [13], [18], [24], [25]
Administración y gestión	- Planeación estratégica - Gestión financiera - Satisfacción laboral - Gestión de la continuidad - Valores - Capacitación y comunicación	[9], [10], [12], [14], [15], [16], [20], [21], [26], [27]

3.2 Modelo estructural de relación entre las prácticas de calidad y el desempeño sostenible de cadenas de suministro

Partiendo del análisis de los resultados de la búsqueda en bases de datos condensado en la Tabla 1, se desarrolló un modelo estructural que representa la relación entre las prácticas de calidad y el desempeño sostenible de las cadenas de suministro (Fig. 2). Así, teniendo como base los resultados de la revisión de literatura, se establece que en este modelo las prácticas de calidad comprenden cinco variables de entrada: gestión de proveedores, aseguramiento de calidad, gestión del producto, gestión del cliente y administración y gestión. La variable respuesta corresponde al desempeño sostenible de la cadena de suministro (ambiental, financiero y social).

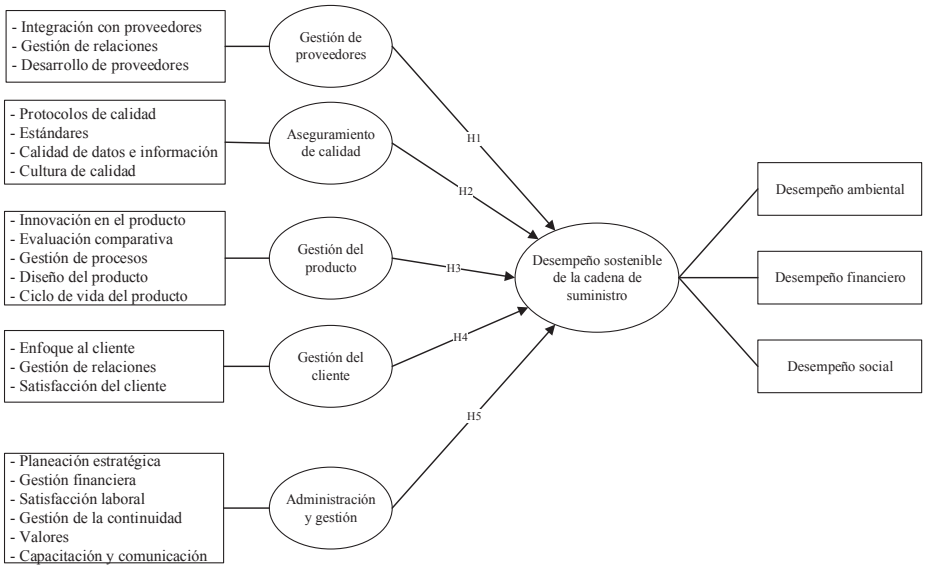

Fig. 2. Modelo estructural de relación entre prácticas de calidad y desempeño sostenible de cadenas de suministro.

Los trabajos previos identificados establecen una relación positiva entre las variables de entrada y la variable respuesta. Así, las hipótesis subyacentes representadas en el modelo son:

H1: La gestión de proveedores tiene un impacto positivo en el desempeño ambiental, financiero y social de la cadena de suministro.

H2: El aseguramiento de calidad tiene un impacto positivo en el desempeño ambiental, financiero y social de la cadena de suministro.

H3: La gestión del producto tiene un impacto positivo en el desempeño ambiental, financiero y social de la cadena de suministro.

H4: La gestión del cliente tiene un impacto positivo en el desempeño ambiental, financiero y social de la cadena de suministro.

H5: La administración y gestión corporativa tiene un impacto positivo en el desempeño ambiental, financiero y social de la cadena de suministro.

La implementación de prácticas de calidad en la gestión de cadenas de suministro genera beneficios para todos los socios [28]. En la medida que las cadenas de suministro analicen y cuantifiquen el impacto de las prácticas de calidad sobre su desempeño global, se contribuye de forma significativa al logro de una producción y consumo

sostenibles [29]. Se requiere del uso de sistemas de medición del desempeño que cuantifiquen en forma balanceada el impacto en los tres pilares de la sostenibilidad.

En el desempeño ambiental se pueden usar indicadores como el porcentaje de producto defectuoso, porcentaje de rechazos y devoluciones, tasa de emisiones, efluentes y residuos, porcentaje de uso de energías renovables [30]. El desempeño social se puede medir a través del nivel de satisfacción de empleados, índice de trabajo decente, satisfacción de partes interesadas, porcentaje de desarrollo de proveedores. El desempeño financiero tiene una mayor práctica y se pueden usar indicadores tradicionales de costo total, costos logísticos, costos de calidad, retorno de la inversión, entre otros [31].

4 Conclusiones

En este trabajo se desarrolló un modelo estructural de la relación entre las prácticas de calidad y el desempeño sostenible de cadenas de suministro, el cual constituye un aporte fundamental al cuerpo de conocimiento del modelado de la gestión de la calidad en cadenas de suministro. En este modelo, las prácticas de calidad se expresan a través de cinco variables de entrada: gestión de proveedores, aseguramiento de calidad, gestión del producto, gestión del cliente y administración y gestión. También, se formularon cinco hipótesis que expresan la relación positiva entre estas variables de entrada y la variable respuesta.

El diseño metodológico utilizado en la búsqueda y selección de trabajos previos a través de criterios de inclusión y exclusión rigurosos permitió seleccionar un conjunto de documentos pertinentes al objeto de estudio en las bases de datos escogidas. Este enfoque de búsqueda sistemática exhaustiva garantiza un proceso centrado en la calidad antes que en la cantidad de fuentes consultadas.

Este trabajo es producto de una línea de investigación en curso en el área de modelado de la gestión de la calidad en cadenas de suministro. Los trabajos futuros se centrarán en el desarrollo de un sistema de ecuaciones estructurales a partir de este modelo y su aplicación en un contexto real. También es de interés integrar técnicas de modelado basado en reglas en una etapa posterior.

Abstract. The Paraguayan Chaco region is in a process of rural electrification, nevertheless, some communities still use power units (generators) for the supply of electricity, while others communities have electricity distribution lines but suffer frequent supply interruptions due to the long distances between the sub-stations and the communities. This is the case of Fuerte Olimpo, which counts with electricity services through a distribution line of 23 kV, which suffers of reliability problems due to its extension of 150 kilometers, and has had 827 hours of electricity supply interruptions in 2019. This study proposes 3 alternatives to operate jointly with the current electricity distribution line: i) with generators, ii) photovoltaic solar energy with battery bank, and iii) through battery banks. The simulation and optimization has been made through the use of HOMER Energy software, in order to determine the most efficient energy source, considering the economic, environmental and technical criteria. The results show that: i) the generators are the most efficient alternative from an economic perspective, with 0,118 USD/kWh of levelized cost of energy (LCOE), but presenting environmental issues. In the other hand, ii) the photovoltaic solar energy has an LCOE of 0,164 USD/kWh, but without greenhouse gases (GHG) emissions. Finally, iii) the mix of electricity distribution line and battery banks has a LCOE of 0,163 USD/kWH and presents null impact to the environment. This study recommends the use of the third alternative as the source of electricity in Fuerte Olimpo, considering the proposed objectives.

Keywords: Renewable energy, isolated localities, COE, HOMER Energy, hybrid system

1 Introducción

1.1 Descripción de la localidad de Fuerte Olimpo – Chaco Paraguayo

El Paraguay cuenta con un superávit de hidroenergía gracias a sus tres centrales hidroeléctricas: ITAIPU Binacional con 14.000 MW de potencia instalada (Paraguay con Brasil), Entidad Binacional YACYRETA con 3.200 MW de potencia instalada (Paraguay con Argentina) y ACARAY propiedad de la Administración Nacional de Electricidad (ANDE), esto conlleva que el Paraguay cuente con una capacidad disponible de 8.810 MW de oferta en su matriz de electricidad; y por otro lado, su demanda máxima en el año 2019 fue de unos 3.550 MW con lo que se puede decir que cuenta con un margen de reserva muy amplio a mediano plazo [1]. El Paraguay cuenta con una alta tasa de acceso a la electricidad 99% de su población, pero existe un paradigma con las

localidades aisladas del sistema interconectado, en su mayoría en el Chaco, como Bahía Negra [2] y Pozo Hondo [3] donde el suministro de energía eléctrica es por medio de centrales térmicas y, por otro lado la localidad de Fuerte Olimpo, la cual se encuentra en condiciones particulares de suministro como se expresa a continuación.

La localidad de Fuerte Olimpo es la capital del departamento de Alto Paraguay. Se encuentra ubicado en el norte del país a orillas del río Paraguay. Dista a 760 km de Asunción. La ciudad está situada en el extremo este del Chaco sobre la margen derecha del río Paraguay y al frente de ella esta Brasil. Cuenta con 5.200 habitantes y su principal actividad socio-económica es la ganadería vacuna y gracias al río Paraguay y sus afluentes, son ricos en la pesca [4].

La localidad cuenta con 1.315 usuarios del servicio de electricidad proveídos por la ANDE y según registros la energía facturada en el año 2019 fue de 16 GWh y esto representó unos USD 250 mil [5]. El suministro es posible gracias a una línea de distribución en 23kV desde la ciudad de Vallemí a una distancia de 150 km, esta distancia ya supera la distancia máxima recomendable según la ecuación de Still [6]. Esta situación de trabajar fuera de los limites recomendables de extensión conllevan a que el suministro tenga varias interrupciones en la continuidad del servicio (fuera de servicios en el año), por citar las interrupciones del servicio accidentales fueron de 541 horas (año 2018) y 469 horas (año 2019) y, por otro lado, los fuera de servicio programados fueron de 61 horas (año 2018) y 358 horas (año 2019) respectivamente [5]. Esta situación de incertidumbre en el suministro y continuidad del servicio de electricidad afecta considerablemente al desarrollo de la localidad.

Ante estas condiciones de suministro con creciente horas de interrupción del servicio anuales, surge la necesidad de una alternativa de fuente de energía o mix de generación in situ con la finalidad de reducir al mínimo las horas sin suministro de energía eléctrica para la localidad y, con ello aumentar la confiabilidad en la continuidad para los usuarios que utilizan la electricidad para la refrigeración de sus alimentos y para el comercio en general, entre otros usos.

Es por ello que este trabajo se centra en analizar las alternativas de obtención de energía eléctrica para los momentos de interrupción de la línea de distribución, buscando operar de forma conjunta de modo a desarrollar un mix de generación más eficiente, confiable y continua. Este caso de estudio se vincula con los desafíos que el Estado debe afrontar y se vincula con los Objetivos de Desarrollo Sostenible (ODS), específicamente el ODS 7, que habla de garantizar el acceso a la energía considerando las potenciales fuentes de generación con que cuenta Paraguay.

Es por ello que este trabajo se enfoca en el análisis de fuentes que puedan suministrar energía eléctrica en los momentos críticos o fuera de servicio de la línea de distribución. La finalidad es encontrar un mix entre: i) grupo electrógeno a diesel, ii) energía solar fotovoltaica y iii) grupo de baterías de respaldo; estas alternativas serian analizadas para su funcionamiento con la línea de distribución actual.

2 Métodos

2.1 Modelado de sistemas con HOMER Energy

El Modelo de Optimización Híbrida para Energía Eléctrica Renovable (HOMER), es el software ampliamente utilizado, disponible en su versión de prueba gratuita y fácil de usar. El Laboratorio Nacional de Energía Renovable (NREL) de EE. UU desarrolló HOMER para simular sistemas conectados a la red y fuera de la red. Su algoritmo computacional se basa en el costo del ciclo de vida. Los algoritmos computacionales de optimización y sensibilidad permitieron evaluaciones tecno-económicas rápidas y sólidas de varias opciones de tecnología de energía renovable (RET) al tener en cuenta el costo de las alternativas de RET y la disponibilidad de recursos de energía renovable. Utiliza la demanda de carga, los recursos, los detalles de los componentes (con los costos), las restricciones, el control de sistemas y los datos de emisión como entrada para simular varias configuraciones factibles y clasificadas por el costo actual neto (NPC).

Normalmente, las simulaciones cubren 8.760 horas de un año típico y un análisis de varios años según el caso de estudio. Los posibles resultados de la simulación HOMER son el tamaño óptimo según el Valor Presente Neto (VPN) y el Costo Nivelado de Energía (COE por sus siglas en ingles), entre otras variables de salida [7].

Los datos de entrada que se utilizaron en este análisis son: i) un perfil de carga diario, ii) alternativas de obtención de energía electrica. Estas son detalladas en el apartado siguiente.

2.2 Descripción del sistema

Las alternativas analizadas para la obtención de generación de respaldo para la localidad fueron planteadas como se puede apreciar en la figura 1, cabe resaltar que todas las alternativas analizadas trabajarían de forma conjunta con la línea de distribución actual:

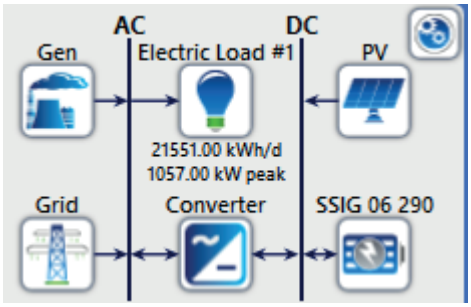

Fig. 1.: Sistema de obtención de energía electrica analizado [1]

[1] Ilustración del esquema de conexión de alternativas de generación, grafico del HOMER Energy

i) Un grupo electrógeno (GE): esta alternativa se considera debido a las condiciones prácticas y de rápida instalación, pero esta alternativa también tiene la desventaja con relación al suministro de combustible, pero esto se puede remediar con unos tanques de reserva (combustible diesel) ubicados estratégicamente a orillas del rio como para su recarga por medio terrestre como por vía fluvial (con el fin de no interrumpir el suministro en temporadas de lluvias donde la localidad se encuentra prácticamente inaccesible por las condiciones precarias de la ruta para su acceso).

ii) Energía solar fotovoltaica (GF): considerando que la radiación en Fuerte Olimpo, datos que fueron importados por el HOMER Energy de la NASA como se muestra en la figura 2. El sistema propuesto estaría compuesto por paneles solares y un banco de baterías de respaldo para los horarios nocturnos y como estabilizadores de potencia en caso de ser necesario.

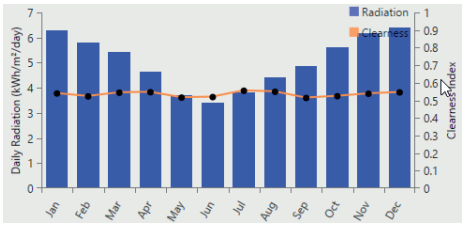

Fig. 2. Radiación solar en Fuerte Olimpo

iii) Banco de baterías (BB): esta alternativa se analiza cómo caso particular consecuente del análisis de energía solar. Esta alternativa considera que el banco de baterías debe operar en conjunto con la línea de distribución y, en caso de una interrupción en el suministro el Banco de Baterías (BB) sería el que suministre energía y posteriormente al restablecimiento de la línea, esta recargaría al Banco de Baterías para el siguiente evento fortuito.

Especificación de sistemas modelados

Las especificaciones técnicas y económicas utilizadas en el análisis con el Homer Energy se presentan en la tabla 1.

Table 1. Especificaciones de alternativas de generación

	Descripción	Especificación
Panel fotovoltaico	Costo de capital (USD/kW) [8]	1.210
	Costo de reemplazo (USD/kW) [8]	1.210
	Costo de mantenimiento y operación (USD/año) [8]	10
	Vida útil	20
Baterías	Costo de capital (USD/kW)[2]	272
	Costo de reemplazo (USD/kW)	272
	Costo de mantenimiento y operación (USD/año)	10
Grupo electrógeno	Costo de capital (USD/kW)[3]	350
	Costo de reemplazo (USD/kW)	350
	Costo de mantenimiento y operación (USD/año) [4]	0,15
	Precio del diesel (USD/litro)	0,796
	Vida útil (horas)	15.000
Línea de distribución 23kV	Costo de capital	No aplica
	Costo de la energía (USD/kWh)	0,0438
	Precio de venta de la energía (USD/kWh)[5]	0,0550

La curva de demanda considerada para la localidad fue proveída por la ANDE [5], y se puede apreciar su comportamiento en la figura 3, ella fue considerada como una curva demanda característica de un día típico (24 horas) que representa a toda la localidad. Para el caso de estudio se tomó un periodo de 10 años y una tasa de descuento del 8% para el VPN.

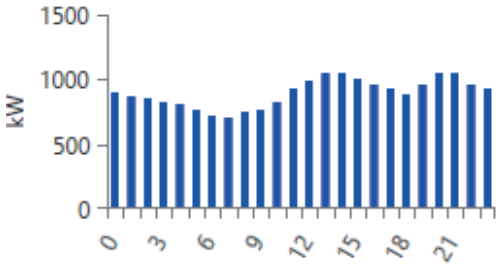

Fig. 3. Curva de demanda característica de Fuerte Olimpo

[2] Los costos de baterías fueron promediados según varias ofertas del mercado en Paraguay.

[3] Los valores de USD/ kW fueron consultados en varios locales y como en Paraguay no hay muchos incentivos para la compra de grupos electrógenos debido a que las tarifas de energía electrica son muy bajos en comparación a la de una energía por medio de grupos electrógenos. El costo para el orden de MW fue proveído por la empresa CATERPILAR

[4] Valor promediado según los estudios en Bahía Negra y Pozo Hondo

[5] La tarifa de venta de energía es un caso particular debido a que los valores son establecidos por el Pliego Tarifario de ANDE (aprobado por decreto del Ejecutivo), donde no se discrimina el lugar de consumo (no hay precios nodales, esto debido al superávit de energía y condiciones particulares del Paraguay)

2.3 Resultados y discusiones

Las alternativas fueron simuladas en el HOMER con los datos de entrada de demanda de energía eléctrica de la localidad y por otro lado los datos técnico-económicos de las alternativas de obtención de energía. Los datos de salida permiten una visión de la alternativa más optima con un enfoque técnico-económico. En la tabla 2 se puede apreciar las condiciones de dimensiones optimas de los generadores con sus correspondiente VPN y COE.

Table 2. Valores de salida del HOMER por alternativas

Alternativa	Descripción	Especificación
Grupo Electrógeno	Potencia (kW)	4.600
	Inversión Inicial (Millones USD)	1,45
	NPC (Millones USD)	12,3
	COE (USD/kWh)	0,116
	Costo de operación (MM USD/año)	1,6
	O&M (MM USD/año)	1,35
	Inversión en combustible (MM USD/año)	0,31
	Combustible diesel (litros)	439,60
	Energía generada (MWh/año)	933
Solar Fotovoltaico + Baterías	Potencia FV (kW)	1.000
	Potencia Conversor (kW)	10.000
	Capacidad del Banco de Baterías (kWh)	70.486
	Inversión Inicial (MM USD)	15,1
	NPC (MM USD)	19,6
	COE (USD/kWh)	0,186
	Costo de operación (MM USD/año)	0,67
	O&M (MM USD/año)	1,23
	Energía generada (MWh/año)	1.378
Grupo de Baterías	Potencia Conversor (kW)	10.000
	Capacidad del Banco de Baterías (kWh)	70.486
	Inversión Inicial (MM USD)	13,9
	NPC (MM USD)	19,3
	COE (USD/kWh)	0,183
	Costo de operación (MM USD/año)	0,809
	O&M (MM USD/año)	1,3
	Energía generada (MWh/año)	727

Según los valores de salida identificados se puede apreciar que entre las alternativas la más ventajosa tomando como indicador el COE sería el Grupo electrógeno con 0,116 USD/kWh, y la menos ventajosa la alternativa de Solar FV y Baterías con 0,186 USD/kWh. Entre todos estos criterios se debería de analizar tanto económica como técnicamente, pero no se debe dejar de lado el criterio ambiental; siendo que en este punto la alternativa de grupo electrógeno se encuentra en desventaja aparte de que se

puede sumar lo referente a la continuidad de suministro de diesel, que también debería ser un criterio válido para analizar. El sistema con energía solar fotovoltaica es comparable en cierto modo a la del mix de la línea con el banco de baterías debido a que ambas evitarían el uso del grupo electrógeno y, a su vez estaría evitando las emisiones de gases de efecto invernadero.

En virtud a la complejidad de la elección de la alternativa que cumpla con los diversos criterios tal como lo expresaron Diemuodeke [7] y Morínigo [3] es necesario un análisis multicriterio considerando varios indicadores, con el cual se puede crear un ranking con las alternativas las cuales cumplan con el objetivo de un mix de generación eficiente, confiable y continua.

3 Conclusión

El Paraguay tiene un gran paradigma con relación a su superávit de energía eléctrica y las localidades aisladas, las cuales no tienen acceso a la energía eléctrica o bien tienen acceso, pero con condiciones de baja confiabilidad lo que incide directamente en la posibilidad de desarrollo económico de las mismas.

Este trabajo realizó un análisis de tres alternativas de obtención de energía eléctrica que trabajarían en conjunto con la línea de distribución para aumentar la confiabilidad y reducir al mínimo posible las interrupciones de la continuidad del servicio de electricidad.

Se identificó que la alternativa del grupo electrógeno es válida técnicamente y en lo económico financiero es la más ventajosa, pero conlleva a efectos colaterales no deseados para el medio ambiente como la emisión de gases de efecto invernadero (de 5.231 Toneladas al año de CO_2).

La otra alternativa fue la de generación solar fotovoltaica la cual es una alternativa ventajosa con relación a la anterior debido a que no tiene emisiones GEI, pero la inversión inicial es elevada y esto conlleva a que el COE sea elevado. Con el fin de reducir la inversión inicial, se analizó el uso de solo un banco de batería para el mix con la línea con lo que se identificaron que los costos son menores y se evita los efectos ambientales no deseados.

El sistema que mejor responde a las necesidades de: i) aumentar la confiabilidad, ii) que su impacto en el medio ambiente sea el menor posible y, iii) que esto represente un costo no tan elevado para el mix; es la de sistema con banco de baterías con un COE de 0,183 USD/kWh. Este valor no es comparable con la tarifa nacional de 0,055 USD/kWh que la ANDE recibe por la energía vendida, pero es una solución que el gobierno debería de plantear con el fin de impulsar el desarrollo económico-social de la localidad considerando su ubicación estratégica como punto de resguardo de la soberanía del Paraguay.

Abstract. The municipal solid waste system is a complex reverse logistic chain which comprises several optimisation problems. Although these problems are interdependent – i.e., the solution to one of the problems restricts the solution to the other – they are usually solved sequentially in the related literature because each is usually a computationally complex problem. We address two of the tactical planning problems in this chain by means of a Benders decomposition approach: determining the location and/or capacity of garbage accumulation points, and the design of collection routes for vehicles. We also propose a set of valid inequalities to speed up the resolution process. Our approach manages to solve medium-sized real-world instances in the city of Bahía Blanca, Argentina, showing smaller computing times in comparison to solving a full MIP model.

Keywords: municipal solid waste; reverse supply chain; integrated allocation-routing problem; Benders decomposition algorithm; valid inequalities.

1 Introduction

Regardless of their size, city councils have the duty to provide efficient service to their constituents. Municipal Solid Waste (MSW) management is a crucial example of such a service. It has direct economic and a social impacts; poor collection service can be both expensive and unsanitary. In this paper, we will focus on a less traditional MSW design called Garbage Accumulation Points (GAP). Instead of providing a "door-to-door" pickup of garbage, constituents have to drop their garbage at specific facility – the GAPs. These facilities can range from collective bins to recycling centres. When using GAPs, MSW management comprises the following design decisions:

– The design of a pre-collection network, which consists in defining the location and capacity of GAPs.

⋆ Corresponding author

– The design and schedule of routes for collection vehicles.

The geographical distribution of GAPs affects the actual route that the collection vehicles must perform. Additionally, the storage capacity of these sites will define the visit frequency in order to avoid overflow. Finally, the availability and type of vehicles[1] affect the distribution and capacity of the GAPs in a (global) optimal solution. Thus, there is a trade-off between the cost of the installation of GAPs and the routing cost; solving both simultaneously is often beneficial [12]. However, solutions in the literature [7, 10, 20] often address each separately. This is due to the complexity of tackling MSW as a whole. Indeed, only solving the design of routes is tantamount to solving a Vehicle Routing Problem (VRP) [23], a well-known NP-hard problem.

In this paper, we propose the following contributions to the field of MSW management with GAPs:

– A novel mathematical model which combines the allocation of bin arrangements to GAPs and defining collection routes (Section 3.1).
– A Benders decomposition-based approach to tackle the resulting problem (Section 4).

The problem we are tackling is an "inventory routing problem" [4]. The resulting formulation is a mixed-integer program (MIP) which is still too large to be tractable. However, we can see it as a combination of two problems:

1. a routing problem, similar to a vehicle routing problem [23]; and,
2. an allocation problem, similar to a nonlinear resource allocation problem [3] – in which the used amount of resource (bin) should be minimized, though not limited.

This *natural* decomposition lead us to use Benders decomposition [1], a well-suited method for problems with this structure. Benders decomposition works by solving such problems in an iterative fashion. First, it solves the *difficult* part to generate a candidate solutions. It then checks this solution against the dual of the *easy* part. From the dual solution, it either terminates, when the dual solution's objective value is equal to an incumbent; or, it generates constraints, called "Benders cuts," which are added to the difficult part and the problem solved anew.

However, we cannot use standard Benders decomposition because the subproblem contains integer variables. Therefore, we use a framework called Unified branch-and-Benders-cut (UB&BC) [17]. This framework is based on a modified Branch-and-Cut (B&C) with callbacks from a commercial solver. In the callbacks, it derives dual information and an upper bound for the subproblem. Using these, it terminates the branch-and-bound tree with a set of *open solutions* – whose objective function value falls below the best upper bound. To find the global optimum, the B&C is followed by a post-processing phase where the framework solves those open solutions to integer optimality.

[1] Mainly capacity, but could also be cost.

We test our model on a real-world use case: the city of Bahía Blanca, Argentina (Section 6). Although the city currently uses a door-to-door collection service, they are interested in switching to GAPs. We simulated instances using data from a survey [5] and provide optimal allocation and routing for a variety of scenarios. Finally, we present our conclusions and future directions in Section 7.

2 A working example

In this section we will present a short example to illustrate the workings of our solution approach. We will use a toy instance shown in Fig. 1a. It comprises: a two-day-horizon, two GAPs, and two vehicles. We also consider two types of waste bins with a storage capacities of 1.1m^3 and 1.73m^3 respectively.

We will now show the iterations the solution algorithm takes.[2] At each iteration, we will report:

- the master solution (routing cost, which includes GAP allocation per vehicle per day);
- the objective function value of the LP relaxation of the subproblem (lower bound);
- the heuristic value (upper bound); and,
- the total cost of the solution.

A graphical representation of the iterations is provided in Figs. 1b to 1d.

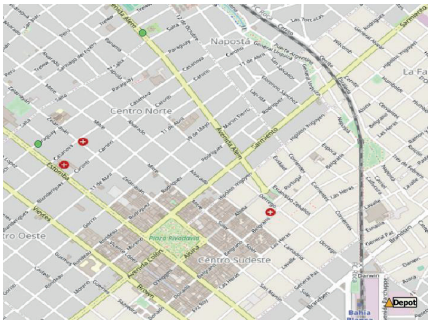
Iteration 1. The first solution uses one vehicles on two days and one vehicle the second day only.

$$v_{0,0} : (0, 2) \to (2, 0)$$
$$v_{0,1} : (0, 2) \to (2, 0)$$
$$v_{1,0} : (0, 1) \to (1, 0)$$

The routing cost is: 494.2. The LP relaxation has an objective function value of 7.96 while the heuristic has a value of 10.48. We add a Benders cut to the master problem and continue.

Iteration 2. The second solution uses two vehicles with different routes during one day:

$$v_0 : (0, 2) \to (2, 0)$$
$$v_1 : (0, 1) \to (1, 0)$$



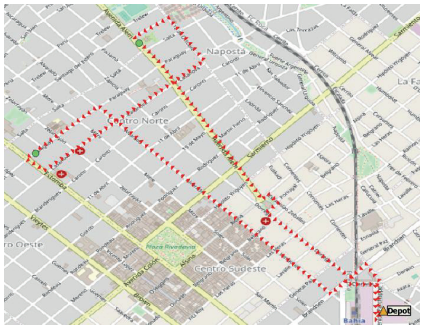
The routing cost is: 381.8. The LP relaxation has an objective function value of 7.06 while the heuristic has a value of 10.48. We add a Benders cut to the master problem and continue.

[2] We use the complete problem (**M1**) augmented with valid inequalities Eqs. (2) to (4). The Benders cuts we generate are "optimality cuts" given by Eq. (8b).

Iteration 3. The third solution found uses a single vehicle with the same route on both days, given by:

$$v_0 : (0, 1) \rightarrow (1, 2) \rightarrow (2, 0)$$

The routing cost is: 316.8. The LP relaxation has an objective function value of 8.58 while the heuristic has a value of 10.48. We add a Benders cut to the master problem and continue.
At this point, the B&C will finish as no improving solution can be found, we can progress to the post-processing.



(a) Location of the depot and the two GAPs (green circles) on the toy instance.

(b) It. 1: The first (blue) vehicle uses its route both days, while the second (red) vehicle only operates on the first day.

(c) It. 2: Both vehicles operate during the first day.

(d) It. 3: Only one vehicle operates during one day

Post-processing. At the start of the post-processing phase, the UB&BC orders solutions according to their lower bound values. In this case, it will process the solutions in reverse order: 3, 2, 1.
Starting with the solution found in Iteration 3, we solve the subproblem to integer optimality. This gives an optimal value of 10.48 – the same as the heuristic. Being an integer value, it can be used to update the upper bound to: 347.28 (routing + delivery).

Then, the framework verifies that the remaining open solutions' values are lower that the new-found upper bound. Both solutions found at Iterations 1 and 2 exceed the best upper bound and are thus skipped.

Our approach has managed to find the optimal solution to the problem. It did so as an integrated algorithm which solved the routing and allocation problems at once.

3 A mathematical model of MSW

3.1 Model formulation

The model has the following sets:

- I: the set of potential GAPs.
- $L = \{l_0, l_1, \ldots, l_{|L|}\}$: is an ordered set of vehicles. We consider a homogeneous and finite fleet of vehicles.
- T: the set of days in the time horizon, which coincides with a week (seven days).
- R: the set of possible visit combinations.
- U: the set of all bin arrangements that can be installed in a GAP.

A potential GAP $i \in I$ is a predefined location in an urban area in which bins can be installed. We define the superset: $I^0 = I \cup 0$, where 0 is the depot from which vehicles start and finish their daily tours, and where the collected waste is deposited. We also define a special notation for the set of edges given a set of nodes: $E(\cdot)$, such that: $E(I) = \{\, (i,j) \mid i \in I, j \in I, i \neq j \,\}$. Bin arrangements are set of bins that are feasible to install in a GAP, respecting the space limitation.

We now define the parameters of the model:

- Q: vehicle capacity.
- c_{ig}: travel time between i to g.
- s_i: service time of GAP i.
- b_i: waste generation per day at GAP i.
- cap_u: capacity of bin arrangement u.
- cin_u: adjusted cost of installing bin arrangement u for the time horizon T.
- α: cost per kilometre of transportation.
- β_r: maximum number of days between two consecutive visits of the visit combination r.
- a_{rt}: 1 if day t is included in visit combination r.
- TL: time limit of the working day.

Notice that cin_u is an *adjusted cost*. This is because we are considering two different level of decision and cost:

1. a strategic decision that involves purchasing and installing the bin arrangements that will last probably for several years; and,
2. a tactical decision which involves the transport costs of the routing schedule [19].

Therefore, the cost assigned to a bin arrangement (cin_u) includes a proportional part of the purchase/installation cost and the maintenance cost. With regards to parameters a_{rt} and β_r, they can be introduced with an example:

Example 1. Let time horizon T be a week – i. e., $T = \{t_1, t_2, t_3, t_4, t_5, t_6, t_7\}$. Then, one possible visit combination $r* \in R$ is $\{t_1, t_3, t_5, t_7\}$. In this case, we have: $a_{r*t_1} = a_{r*t_3} = a_{r*t_5} = a_{r*t_7} = 1$, and, conversely: $a_{r*t_2} = a_{r*t_4} = a_{r*t_6} = 0$. Thus, the maximum number of days between two consecutive visits that this combination has is two days: $\beta_{r*} = 2$, and the chosen bin arrangement for this GAP must be able to store the waste generated in two days. (A similar consideration is performed in [12].)

Finally, we define the following decision variables:

- x_{iglt}: binary variable set to 1 if vehicle l performs the collection route between GAPs i and g on day t, 0 otherwise.
- v_{iglt}: continuous variable representing the load of vehicle l along the path between GAP i and g on day t.
- m_{ir}: binary variable set to 1 if visit combination r is assigned to GAP i, 0 otherwise.
- n_{ui}: binary variable set to 1 if bin arrangement $u \in U$ is used for GAP i, 0 otherwise.

We can now present the mathematical model for the MSW management problem:

$$\min \quad \sum_{\substack{i\in I\\ u\in U}} n_{ui}\ cin_u + \alpha \sum_{i,g\in E(I^0)} c_{ig} \left(\sum_{\substack{l\in L\\ t\in T}} x_{iglt} \right) \qquad (\mathbf{M1})$$

$$s.t. \quad \sum_{u\in U} n_{ui}\ cap_u \geq \sum_{r\in R} b_i m_{ir} \beta_r \qquad \forall\ i \in I \quad (1a)$$

$$\sum_{u\in U} n_{ui} = 1 \qquad \forall\ i \in I \quad (1b)$$

$$\sum_{r\in R} m_{ir} = 1 \qquad \forall\ i \in I \quad (1c)$$

$$\sum_{\substack{g\in I^0, g\neq i\\ l\in L}} x_{iglt} - \sum_{r\in R} a_{rt} m_{ir} = 0 \qquad \forall\ t \in T,\ i \in I \quad (1d)$$

$$\sum_{i\in I^0, i\neq q} x_{iqlt} - \sum_{g\in I^0, g\neq q} x_{qglt} = 0 \qquad \forall\ q \in I^0,\ l \in L,\ t \in T \quad (1e)$$

$$\sum_{i\in I} x_{0ilt} \leq 1 \qquad \forall\ l \in L,\ t \in T \quad (1f)$$

$$\sum_{i,g\in E(I^0)} (c_{ig} + s_i)\ x_{iglt} \leq TL \qquad \forall\ l \in L,\ t \in T \quad (1g)$$

$$v_{iglt} \leq Q\ x_{iglt} \qquad \forall\ (i,j) \in E(I^0), l \in L,\ t \in T \quad (1h)$$

$$\sum_{i \in I^0, i \neq g} v_{iglt} + b_g \sum_{r \in R} (m_{gr}\ \beta_r) \leq \sum_{i \in I^0, i \neq g} v_{gilt} + Q \left(1 - \sum_{i \in I^0, i \neq g} x_{iglt}\right) \quad \forall\ g \in I,\ l \in L,\ t \in T \tag{1i}$$

$$v \geq 0; n, x, b \in \mathbb{B}$$

The objective function is the sum of the routing cost and the adjusted cost of installing bins. Equation (1a) limits the maximum amount of garbage that can be accumulated in a GAP to the installed capacity of the bin arrangement. Equation (1b) enforces that one bin arrangement has to be chosen for each GAP. Equation (1c) establishes that one visit combination is assigned to each GAP. Equation (1d) ensures that each GAP is visited by the collection vehicle the days that corresponds to the assigned visit combination. Equation (1e) ensures that if a vehicle visits a GAP, it leaves the GAP on the same day. Equation (1f) states that every vehicle can be used at most once a day. Equation (1g) guarantees that a tour does not last longer than the allowable time limit associated with the working day of the drivers. Equation (1h) limits the total amount of waste collected in a tour to the vehicle capacity. Equation (1i) establishes that the outbound flow after visiting a GAP equals the inbound flow plus the waste collected from that GAP and, thus, also forbids subtours.

3.2 Valid inequalities

The model presented above for the MSW (**M1**) is still a difficult problem. In particular, it contains a lot of *symmetric solutions.* Two solutions are said to be symmetric if they have the same objective function value but different variable assignments. Consider the following: during a given day, two trucks undertaking the same collection route would have the same cost. There is no way for the solver to omit one of them.

One way to address this issue is to add Valid Inequalities (VIs) to the model. A VI is a constraint that reduces the feasible polytope of the problem without removing every optimal solution. We decided to focus on VIs for the routing part of the problem because the allocation part is *easy* in comparison. For examples of VIs in the context of vehicle routing problems, we refer the interested reader to [6].

One thing to remember is that our graph is asymmetric. Therefore, we do not need to address symmetries in routes with the same GAPs. We have developed the following valid inequalities to remove as much symmetry from the optimal solutions as possible.

Empty start. A vehicle must start its tour unloaded. This prevents solutions with different *delivery plans* – when a vehicle finishes its collection tour below full capacity, we can consider another solution where the vehicle starts with any amount less than the difference.

$$v_{0glt} = 0, \forall\ g \in I,\ l \in L,\ t \in T \tag{2}$$

Vehicle ordering. We impose that a vehicle with index l can only leave the depot if the vehicle with index $l-1$ has. In the case where a solution does not use all available vehicles, we can consider swapping an unused vehicle with a used one. For brevity, we define: $L' = L \setminus \{0\}$, as the set of vehicles minus the first one.

$$\sum_{i \in I} x_{0ilt} \leq \sum_{i \in I} x_{0ipt}, \forall\ l \in L',\ p = l-1,\ t \in T \tag{3}$$

Furthest visit. We assign the furthest GAP from the depot to the first vehicle. Because each GAP must be visited at most once a day, so does the furthest. Because only one vehicle can visit each GAP on a given day, we can forbid others vehicle than the first vehicle – using L' defined above – to visit the furthest GAP.

$$\sum_{i \in I, t \in T} x_{iglt} = 0, \forall\ l \in L', g = \underset{i \in I}{\operatorname{argmax}}\, c_{0i} \tag{4}$$

4 A resolution approach based on Benders decomposition

The classic Benders decomposition was devised in [1] for addressing large MIPs that have a characteristic *block diagonal* structure. In summary, it starts by decomposing the *original problem* into a *master problem* and a *subproblem*. The master problem is a relaxation of the original problem used to determine the values of a subset of its variables. It is formed by retaining the *complicating variables*, and projecting out the other variables and replacing them with an *incumbent*. The subproblem is formed around the projected variables and a parameterised version of the complicating variables. By enumerating the extreme points and rays of the subproblem, the algorithm defines the projected costs and the feasibility requirements, respectively, of the complicating variables. Because this enumeration is seldom tractable, the algorithm proceeds in the following manner:

1. It solves the (relaxed) master problem to optimality, which yields a *candidate solution.*
2. This candidate solution is used as a parameter in the subproblem.
3. The resulting problem is solved to optimality and, using LP duality, a set of coefficients are retrieved.
4. These coefficients are used to generate a constraint, called a "Benders cut," which is added to the master problem.
5. If the objective function value of the subproblem is equal to the incumbent value in the master problem, the algorithm stops. Otherwise, it repeats from point 1. using the master problem with the additional constraint.

One key limitation of the classic Benders decomposition is that the subproblem cannot contain integer variables. This is because of point 3. above: the method needs to use LP duality, which is not well-defined for MIPs. We use a recent framework called Unified branch-and-Benders-cut (UB&BC) [18] to bypass this issue. This new framework operates by using a modified B&C where, at each integer node, it:

1. solves the LP relaxation of the subproblem to get a lower bound and generate Benders cuts; and,
2. uses a heuristic to determine if the master solution is feasible and, if yes, a valid, global upper bound.

The second point is key: by maintaining a valid upper bound, the framework ensures that no optimal solution is removed during the search. However, this leads to having a set of *open solutions* after finishing the B&C tree – solutions whose objective function value falls between the lower and upper bound. Thus, the UB&BC finishes by a *post-processing phase* during which subproblems associated with open solutions are solved to integer optimality. The combination of maintaining a global upper bound and using a post-processing phase enables the framework to find an optimal solution.

As stated in Section 3.1, the problem addressed in this work comprises two characteristic decision-making problems in MSW. On the one hand, the allocation of bins in the GAPs and, on the other, the design and schedule of routes for the collection vehicles. This division can be exploited by applying Benders decomposition. The bins allocation equations are moved to the subproblem while the master problem aims at designing the schedule and routes of the collection vehicles.

4.1 Creating the subproblem

The subproblem, which aims at allocating the bins of each GAP, is an integer programming problem:

$$q(\overline{m}) = \min \quad \sum_{\substack{i\in I\\ u\in U}} n_{ui}\ cin_u \qquad (\mathbf{SB})$$

$$s.t. \quad \sum_{u\in U} n_{ui}\ cap_u \geq b_i \sum_{r\in R} \overline{m_{ir}}\ \beta_r \qquad \forall\ i \in I \qquad (5a)$$

$$\sum_{u\in U} n_{ui} = 1 \qquad \forall\ i \in I \qquad (5b)$$

$$n \in \mathbb{B}$$

We define the positive continuous variables δ_i and unrestricted continuous variables γ_i, the dual variables of Eqs. (5a) and (5b) respectively. The dual formulation of the LP relaxation of (**SB**), which will be used to generate cuts, is then:

$$q^{LP}(\overline{m}) = \max \quad \sum_{i\in I}\left(\gamma_i - \delta_i b_i \sum_{r\in R}(\overline{m_{ir}}\beta_r)\right) \qquad (\mathbf{LP})$$

$$s.t. \quad \gamma_i - \delta_i \sum_{u\in U} cap_u \leq \sum_{u\in U} n_{ui} \qquad \forall i \in I \qquad (6a)$$

$$\delta, \gamma \geq 0$$

Heuristic for the subproblem. In order to apply Benders decomposition when the subproblem has integer variables, an efficient method for solving the subproblem is required. Therefore, we devised a rounding heuristic procedure based on the LP relaxation of the subproblem:

1. We solve the LP relaxation of (**SB**). The (relaxed) solution will contain n_{ui} with fractional values.
2. We estimate the *joint fractional capacity* K_i^f of each GAP using:
$$K_i^f = \sum_{u \in U} n_{ui}\ cap_u \tag{7}$$
3. We define a feasible (non-fractional) bin arrangement $u \in U$ for each GAP by finding the bin arrangement with minimal cost among those with storage capacity larger than K_i^f. It is guaranteed that there will always be a bin arrangement which respects this rule since considering Eqs. (5b) and (7) implies that: $K_i^f \leq cap_{u*}, \forall\ i \in I$, where $u* = \text{argmax}_{u \in U}\{cap_u\}$.

4.2 Stating the master problem

The master problem retains the same constraint structure as (**M1**) but the bin allocation part is replaced by an incumbent variable q. Let us consider the set of extreme points ($\mathcal{O}$) and extreme rays ($\mathcal{F}$) of the LP relaxation of (**SB**). These generate the optimality (8b) and feasibility (8a) cuts, respectively. Therefore, the master problem is:

$$\min \quad \alpha \sum_{i,g \in E(I^0)} c_{ig} \left(\sum_{\substack{l \in L \\ t \in T}} x_{iglt} \right) + q \tag{**MPB**}$$

$$s.t. \quad \text{Eqs. (1c) to (1i) and (2) to (4)}$$

$$\sum_{i \in I} \left(\gamma_i^f - \delta_i^f b_i \sum_{r \in R} (\beta_r m_{ir}) \right) \leq 0 \qquad \forall\ f \in \mathcal{F} \tag{8a}$$

$$\sum_{i \in I} \left(\gamma_i^f - \delta_i^o b_i \sum_{r \in R} (\beta_r m_{ir}) \right) \leq q \qquad \forall\ o \in \mathcal{O} \tag{8b}$$

$$v \geq 0; q \in \mathbb{R}; x \in \mathbb{B}$$

5 Literature review

Allocation of bins and routing problems have been thoroughly studied as separate problems in the MSW related literature [16]. Comprehensive reviews of the study of these problems separately can be found in [20] and [10], respectively. However, the number of works considering integrated approaches is more scarce.

Among the works that consider an integrated approach, [14] presented a study case of the Tunisian city of Sousse, considering uncertainty in waste generation at GAPs. They proposed a transformed formulation to handle stochastic

waste generation and solved the problem in a heuristic fashion: first they applied the k-means clustering algorithm to group the GAPs into sectors and later they applied an exact model solved with CPLEX to determine both the number of bins and the collection route of each sector. They consider that all GAPs are to be collected daily.

Another example is [12], which proposed an integrated approach where the bins allocation problem is solved jointly with the routing schedule. The authors compare different methods to solve this problem based on a Variable Neighbourhood Search (VNS) algorithm, for solving the problem hierarchically – i. e., first solving the bin allocation and then the routing and *vice versa* – and integrated approaches. They found that integrated approaches overcome hierarchical ones.

A further complex approach is presented in [13] for solving an integrated model that aims to simultaneously locate GAPs, size the storage capacity of each GAP (allocate bins) and set the weekly collection schedule and routes in the context of collaborative recycling problem. They solved this problem with an Adaptive Large neighbourhood Search algorithm based on Hemmelmayr's implementation [11]. They performed a sensitivity analysis for several of the parameters, such as available vehicle capacities, visiting schedules or GAPs' storage capacities.

Although integrated models have proven to efficiently handle the trade-off [7, 9], others works have tackled these problems in a sequential fashion. For example, [8] solved the GAP location with while considering that bins of incompatible types – i. e., that cannot be collected by the same vehicle – are not located in the same GAP. Then they applied an heuristic zoning algorithm to define the routes while minimising the number of required vehicles and the total distance. Finally, [21] solved a multi-objective bins allocation problem in which one of the objectives was to minimise the required collection frequency.

Differently from the tactical problem that we address in this paper, other authors have used Bender's decomposition approaches to deal with optimization problems of the strategic level of the MSW logistic chain, mainly considering stochastic parameters (which is a traditional application area of Bender's decomposition). For example, [22] used Bender's decomposition to model a logistic chain of MSW in which organic waste in send from sources into treatment plants to generate power. Uncertainty is considered in waste generation, and power price and demand. Another case are [15], who applied Bender's decomposition to optimize the location and capacity selection of waste transfer stations when considering uncertainty in the operational cost of the stations.

6 Computational experiments

The instances used for these tests are based on simulated scenarios of the city of Bahía Blanca, Argentina. Although this city still has a door-to-door collection system, the local government and citizens are interested in studying more efficient collection systems that allow them to reduce the high logistic costs. In this sense, a community bins-based will simplified the required collection logistic [2, 5]. Particularly the location of 76 GAPs in a central neighbourhood of the

city and the generation rate were obtained from a recent field work in a central neighbourhood of the city [5]. We consider a *homogeneous VRP* by using the standard collection vehicle of Bahía Blanca, a $20\,\mathrm{m}^3$ bin-tipper truck. The GAPs can hold three types of commercial bin with purchasing and maintenance cost (cin_u) 2.76, 3.53 and 5.24 monetary units (m.u.) and capacities (cap_u) 1.1, 1.73 and $3.1\,\mathrm{m}^3$, respectively. Information about the travel time between GAPs was estimated with Open Source Routing Machine[3] using the approach proposed by Vázquez Brust [24]. The algorithms are implemented in Python 3.5, and we use a UB&BC framework called BranDec[4] v0.7. For the benefit of the scientific community, we open-sourced the instances used for the experimentation[5] and implementation. The solver used is CPLEX v12.7 in its default configuration, we disable heuristics when running the UB&BC. We ran the experiments on a computer with Intel Gold 6148 Skylake CPU@2.4GHz and a 4GB RAM limit.

We divide the computational experimentation in two parts. In Section 6.1 we deal with small instances in order to asses the value of the proposed valid inequalities in the resolution approach. Then, in Section 6.2 we explore the performance of the proposed Benders approach in comparison to full MIP when solving more complex instances.

6.1 The value of valid inequalities

In order to explore the impact of valid inequalities in the resolution process we construct instances composed by five GAPs and the Depot. These sample of five GAPs were selected with QGIS Random Selection tool. We consider scenarios with two vehicles and two bin arrangements per GAP, the instances are formatted as "$I/T/n$," where n is the instance number. Figure 1 report the results of solving the resulting problem with:

MIP CPLEX using (**M1**);
MIP + VIs CPLEX using (**M1**) augmented with VIs (2) to (4);
BD our Benders approach; and,
BD + VIs our Benders approach augmented with VIs (2) to (4).

We ran five iterations of each configuration and report the minimum solve time. We can see in Fig. 1 that the VIs are necessary to have reasonable solve times. Both the MIP and our Benders approach benefit from them. When instances grow in size, that is when the time horizon is greater than two days, version with VIs do not manage to solve most instances. This experiment is not enough to tell for certain whether the Benders approach is better than MIP.

6.2 Using more bin arrangements

The complexity of the problem grows with the size of the instance becoming increasingly time consuming for the algorithm. Indeed, we now use a larger set of bin arrangements (set U) for the GAPs in order to have a more complex subproblem with a larger number of binary variables. In Fig. 2 we can see the

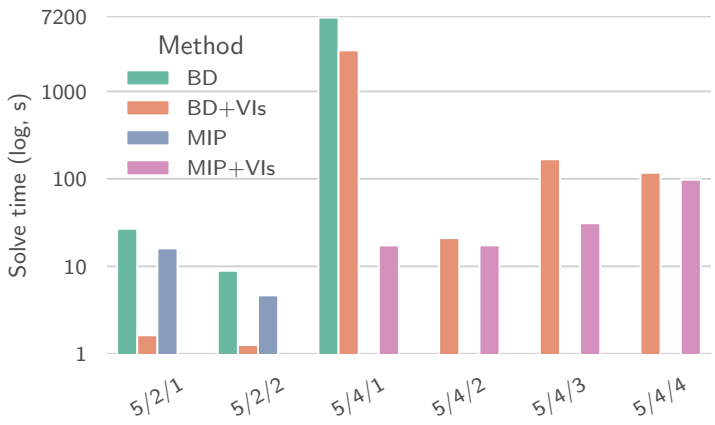

Fig. 1: Results of using different methods, with or without VIs, to solve a set of reduced instances.

time taken to find the optimal solution on a set of instances by our approach (BD) vs. solving the full MIP model with CPLEX (MIP). All the solutions have the valid inequalities (2) to (4) included. Our approach is, on average, more than one order of magnitude faster than using a full MIP. We are able to solve instances up to 7 GAPs, which the MIP cannot.

7 Conclusion

Municipal solid waste management is a critical issue in modern cities. Besides the direct environmental and social problems that can arise when it is mishandled, it usually represents a large portion of the municipal budgetary expense. Therefore, intelligent decision support tools that can efficiently provide this service to the citizens while also reducing the cost of the system can be a major asset for decision makers. This work addresses two common tactical problems that arise in the reverse logistic chain of solid waste: the design of a pre-collection network and the routing schedule of collection vehicles. These problems, which are usually solved individually in the related literature, are interdependent in the sense that the solution to one of the problem affects the other.

This work proposed an integrated approach that solves both problems simultaneously, making the trade-off an intrinsic element of the model. In particular, a new MIP formulation, valid inequalities and resolution approach based on Benders decomposition, using unified branch-and-Benders-cut, were proposed. Since the subproblem contains integer variables, we devised a heuristic for solving the bin allocation problem. Our approach was able to solve real-world instances in the city of Bahía Blanca. Tests performed on small instances showed the competitiveness of the valid inequalities to speed up the resolution process. Then, the resolution of larger instances showed that the proposed Benders approach was more competitive than full MIP. While not yet able to solve full-size instances, our approach holds promises to scale beyond a traditional MIP approach.

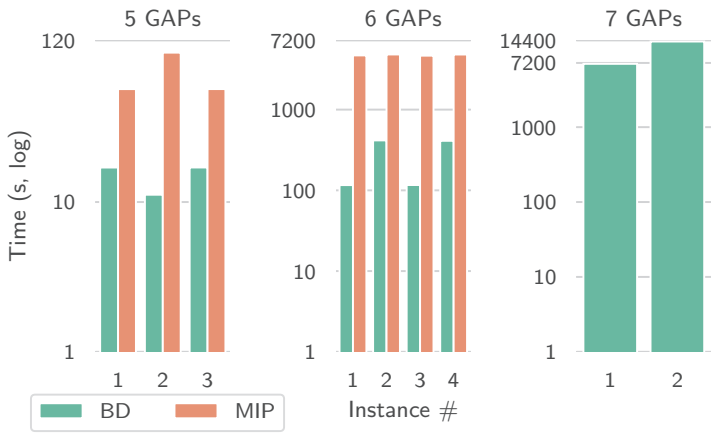

Fig. 2: Comparison of MIP vs. our Benders approach on a variety of scenarios. We report the time in log scale.

Future work includes expanding computational experiments with larger real-world instances to test the scalability of the approach. Another research line is to consider an allocation-first routing-second method. In that case, the master problem would be comparatively simpler than the subproblem. Such an approach would require efficient vehicle routing heuristics to work. We could also explore heterogeneous fleet of vehicles. Indeed, the city of Bahía Blanca already owns a fleet of vans of small capacity for spot operations.

Proposal of a Heuristic for Cluster Analysis with Application in Allocation of Anaerobic Co-Digesters for Biogas Production

Monique Schneider Simão[1], José Eduardo Pécora[1], Gustavo Valentim Loch[1]

[1] Federal University of Paraná, Curitiba, Paraná, Brazil
monique.schneider@ufpr.br

Abstract. Cluster analysis refers to optimally segmenting a set of entities, and there are several types of algorithms to reach this purpose. It can be applied in decision making, machine learning, data mining, and pattern recognition. This work aims to develop a simple and fast partition heuristic to solve the cluster analysis problem, where the optimality criteria are the smallest distances between the vertices of the same cluster. To verify the proposed heuristic, tests were made in instances ranging from 20 to 5000 nodes and different degrees of complexity. The developed algorithm can be applied to large size datasets were time could be a limitation factor. As an example of application, the heuristic developed was used to choose the location for installing anaerobic co-digesters for the production of biogas in the state of Paraná, Brazil.

Keywords: Cluster Analysis, Heuristics, Biogas.

1 Introduction

Cluster analysis involves optimally partitioning a given set of entities into a predetermined number of mutually exclusive clusters, where the criterion of optimality depends on the application in which the grouping is being employed [1]. Clustering is useful in several exploratory analyses, such as decision making, machine learning, data mining and pattern recognition [2].

Clustering algorithms can be divided into two main approaches: hierarchical and partition. The hierarchical approach produces a series of nested segments, agglomerating or dividing the previous clusters to achieve the desired segmentation. The partition system performs segmentations that optimize a given objective criterion or function. For each approach, there are numerous types of algorithms (genetic algorithm, ant colony, k-means, etc.) that have characteristics that make them more appropriate for solving a particular kind of problem [3].

Within the ways to solve cluster analysis problems is the use of heuristics, which are methods for solving specific problems that use shortcuts to produce solutions that, although not always optimal, are sufficiently adequate in a timely manner. This work aims to develop a simple and fast heuristic to partition a given dataset into a predefined number of clusters in a way that the sum of distances within all clusters is the

smallest possible. We tested the proposed heuristic in instances ranging from 20 to 5000 nodes and different degrees of complexity. This paper's main contribution is present a heuristic that could be applied to large size datasets where time may be a limitation factor and high accuracy isn't crucial. Examples of this work application include multiple facility allocation where an extensive area is considered and the installation of a facility where it can be utilized by a number of persons large as possible (e.g., medical center, supermarket, etc). We applied the heuristic to find the best location for biogas production in the state of Paraná, Brazil. This application was chosen due to the current relevance of renewable energy sources as an alternative to meet the global energy demand without significant environmental impacts [4].

2 Problem definition

The optimization model used was proposed in [3], which was based on the work [1] and is described by (1) to (7).

Parameters:
$k \in K = \{1, ..., M\}$ defines the sets of cluster;
$i, j \in V = \{1, ..., N\}$ defines the sets of points;
M is the total number of clusters;
N is the number of vertices.

Decision variables:
x_{ik} is a binary variable whose value is equal to 1 if the vertex i is in cluster k and 0 otherwise;
y_{ij} is the binary variable whose value is equal to 1 if the vertices i e j are in the same cluster and 0 otherwise;
d_{ij} is the distance between vertices i e j.

Objective Function:

$$Min \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} d_{ij} y_{ij} \tag{1}$$

Subjected to:

$$\sum_{k=1}^{M} x_{ik} = 1, \qquad \forall\, k \in K \tag{2}$$

$$\sum_{i=1}^{N} x_{ik} \geq 1, \qquad \forall\, i \in V \tag{3}$$

$$y_{ij} \geq x_{ik} + x_{jk} - 1, \forall\, i \in V, j \in \{i+1, \dots, N\}, k \in K \tag{4}$$

$$y_{ij} \geq 0, \forall i \in V, j \in \{i+1, \dots, N\} \tag{5}$$

$$x_{ik} \in \{0,1\} \ , \forall \ i \ \in V, k \ \in K \tag{6}$$

$$y_{ij} \in \{0,1\} \ \forall \ i,j \ \in V \tag{7}$$

The objective function (1) aims to minimize the total distance among vertices of the same cluster. The set of constraints (2) assure that each vertex belongs to only one cluster. The set of constraints (3) assure that each cluster has at least one vertex. The constraints (4) and (5) assure that the variable y_{ij} is equal to 1 if both x_{ik} and x_{jk} are equal to 1. The domain of the variables is defined by equations (6) and (7).

3 Proposed heuristics

The methodology developed in this paper was grounded on the work [5] where the authors proposed an algorithm that search for spikes of density, based on the assumption that clusters are density spikes distant from each other and surrounded by a less dense neighborhood. The heuristic proposed in this work and in [5] works only for data defined by a set of coordinates.

First, to identify which regions had the highest density of attributes, the search space is divided into a number of squares, defined as follows: (i) to form the squares, the *X* and *Y* axes are first subdivided into *n*z* segments, were *z* is arbitrarily defined and *n* is the number of clusters desired; (ii) the number of subdivisions of each axis is increased until the sum of attempts that did not improve the objective function is equal to a predetermined value.

Then, to determine the density, sum the quantity of a particular attribute (e.g., points, cities, production potential, number of consumers, etc.) in each region. In sequence, order the regions in relation to density in a decreasing way, after that, select the first *n* regions.

Finally, cluster's centroid is determined by searching, in each of the *n* regions selected previously, the point that has the smallest accumulated distance from the other points belonging to the same square. The heuristic's pseudocode is presented below.

3.1 Pseudocode

While the maximum number of attempts without improvements isn't reached do:

Divide the search space by *n*z*, where $z \geq 0$ and *n* is the number of clusters;
Sum the points or attributes within each region to obtain the density;
Select the *n* densest regions;
For each area selected above, define as cluster's centroid the point with the smallest sum of distances from other points in the same region;
Assign the remaining points to the cluster of the nearest centroid;
Verify if the restrictions were satisfied;
Evaluate the objective function;
If the actual objective function value is better than the previous, then set the best cluster's configuration as the actual solution;

If the value is not better, then add one to the number of attempts without improvement;
Add one to z's value;
Return the best cluster configuration.

4 Results

The method was tested on instances generated by the authors. To obtain the exact solution for the clustering problem on these instances, we developed a program in C++ and solved it using CPLEX 12. The results obtained are in Table 1.

Table 1. Results for the exact solution.

The algorithm for the heuristic solution was implemented in Python and executed on an Intel Core i5 1.80GHz RAM notebook. We set the initial value of z as 1 and increased it by one until reach 5 attempts without improvement. The results obtained by the proposed heuristic, along with the comparison with the exact results, are shown in Table 2.

Table 1 show that the heuristic obtained values near the optimal solution obtained by the exact method in a much smaller time. It is also possible to verify that in the cases where the exact method couldn't reach the optimal solution, the value achieved by the heuristic was better. The heuristic proposed was also tested in larger instances, obtained in [6]. The values of the objective functions and the test execution time for these instances are shown in Table 3, and the distribution of clusters for instances "S1" and "S2" is illustrated in Figure 1.

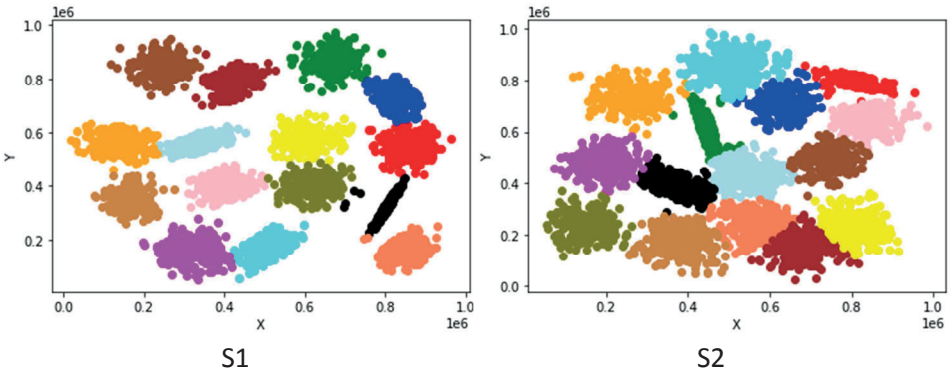

Fig. 1. Results for "S1" and "S2" instances.

For "S" instances the algorithm´s performance varied significantly as the size of the data set increased and several points were assigned to the wrong clusters, as can be seen in Figure 1, which shows the distribution of the points. This problem could be solved by considering the distance between the density spikes, selecting as clusters the densest locations that are the most far from the others. However, the attempts made with this methodology had the execution time as a limiting factor, both because Python is an interpreted language that needs special compilation libraries to run faster, and the configuration of the computer used to run the tests.

Table 3. Results for the "S" instances.

[1]Value of the objective function calculated using the ground truth centroids found in [6]

5 Application and final considerations

The developed heuristic was applied to choosing locations for installing anaerobic co-digesters for the production of biogas in the state of Paraná, Brazil. The solution aimed to minimize the transport distances, the total cost of the supply chain, and the associated carbon emissions. The main logistical activities in the biogas supply chain are substrate harvesting or collection, substrate storage, substrate transport, biogas production, biogas transport, and consumption of biogas [7].

Geography and distance can be essential factors because the transformation of biomass into energy is highly dependent on geographical factors since the supply of substrates and the points of demand for biogas are often widely dispersed. The use of cluster analysis to solve this problem is supported by the fact that deploying regional or centralized anaerobic digesters is an effective way to serve various rural establishments and consumers [8].

Biogas is formed in nature by the biological degradation of organic matter under anaerobic conditions. The main components of biogas are methane and carbon dioxide, which can be captured to generate energy in heat and electricity. The generation of biogas can be maximized by using techniques such as co-digestion, which is the simultaneous digestion of two or more organic substrates. Co-digestion can increase biogas production by 25% to 400%, compared to isolated digestion of the same substrates [9]. In addition to increased biogas production, co-digestion also provides the following benefits: (i) improves the process stability; (ii) decreases the concentration of inhibitory substances; (iii) better balance of nutrients and moisture; (iv) increase the organic load; and (v) economic advantages due to equipment and cost-sharing [10].

In this case study, the choice of raw materials that will compose the mixture fed in the co-digester was made based on the article [11], where the tailings produced in Brazil were quantitatively and qualitatively analyzed to list which ones had the greatest potential for biogas generation. According to [11], more than 60% of the total biogas generation potential in Brazil comes from cattle manure, followed by sugarcane vinasse, swine manure, and poultry manure.

We obtained data on the number of heads of each of the types of farming considered and of tons of sugarcane produced in each of the 399 Paraná's cities from [12]. From these data, we calculated the biogas production potential for each city in the state. To calculate the potential for biogas production from the manure of different animals we used equation (8) obtained from [11].

$$Q_{CCH4} = Q_{SCH4} = Q_{PCH4} = \frac{I_M . NA . f_m . \varepsilon}{1000} \quad (8)$$

Where:

Q_{CCH4} is the potential for biogas production from cattle manure (m³/year);
Q_{SCH4} is the potential for biogas production from swine manure (m³/year);
Q_{PCH4} is the potential for biogas production from poultry manure (m³/year).

I_M is the manure generation rate of the animal herd (kg/year), the adopted values were: 10 for cattle manure, 2,25 for swine manure and 0,18 for poultry manure. These values were found in [13] *apud* [14] and [15];

NA number of animal herds in all territory;

f_m factor of biogas production by manure type (m^3CH_4/t), the adopted values were: 12 for cattle manure, 12 for swine manure and 27 for poultry manure. These values were found in [13] *apud* [14] and [15];

ε collection efficiency in bio-digester (adopted to be 90% as in [11]).

To calculate the potential for biogas production from sugarcane vinasse we used equation (9), obtained from [11].

$$Q_{VCH4} = P_V . T_S . COD_V . E_{fv} . f_V . E_{cV} \quad (9)$$

Where:

Q_{VCH4} is the potential for biogas production from sugarcane vinasse (m^3/year);;

P_V is the vinasse production by mass unity of sugarcane (m^3/year);

T_S is the sugarcane produced amount (tons) ;

COD_V is the typical COD for vinasse, whose value was assumed as equal to 35,5 kg/m^3 [16];

E_{fv} is the removing efficiency of vinasse organic load in an anaerobic reactor, whose value was assumed as equal to 62% based on [17];

f_V is the specific factor of biogas production per mass of COD removed in the anaerobic reactor, whose value was assumed as equal to 0,29 $m^3/kgCOD_{removed}$ and obtained from [18];

E_{cV} is the collecting efficiency of biogas in the anaerobic reactor, assumed as 90%.

The total methane production potential of each city was calculated using equation (10). The map of production potential's obtained is shown in Figure 2.

$$Pot_{ch4} = Q_{VCH4} + Q_{CCH4} + Q_{SCH4} + Q_{PCH4} \quad (10)$$

Where:

Pot_{ch4} is the total biogas production potential (m^3/year);

The heuristic developed was used to segment the state of Paraná into seven clusters to minimize transport distances and the total cost of the biogas generation supply chain. The number of cluster was defined arbitrarily.

First, to identify which regions had the highest potential density for biogas production, the geographical space of Paraná was subdivided into a number of segments, the initial value of z was set as 0.5. The number of subdivisions of each axis was increased by one until reach five attempts that failed to improve the objective function. Then, to determine the density of the regions previously obtained, each city's total biogas production potential in the region was added. The regions were then ranked

according to the density of the biogas production potential in a decreasing way. After that, the first *n* regions were selected.

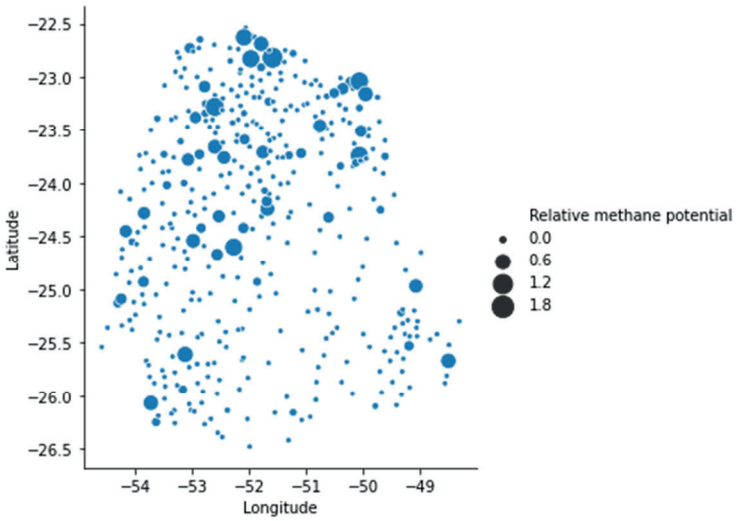

Fig. 2. Relative methane production potential for each city in the state of Paraná, Brazil.

To choose the centroid we considered not only the distance from other points but also the production differences, to do so, we multiplied the distance by the methane potential, making the centroids closer to high production points. Finally, each city was assigned to the clusters of the nearest centroid. The results obtained are shown in Figure 3.

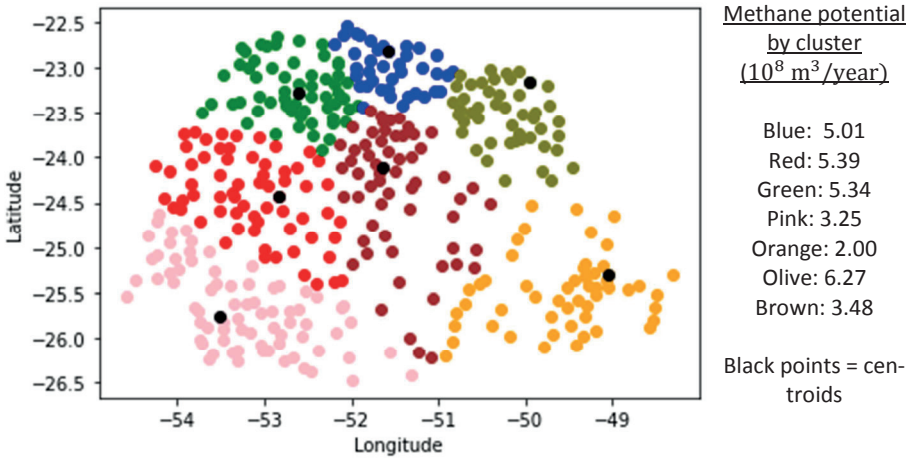

Fig. 1. Application of the cluster analysis heuristic for an anaerobic co-digester allocation in the state of Paraná, Brazil.

Comparing Figures 2 and 3, it is possible to observe that the algorithm was able to identify as centroid the spots with higher potential for methane production. We can conclude that despite the simplicity of the proposed heuristic, it can obtain satisfactory results for different sizes of spaces and numbers of clusters. Also, the technique is flexible and can be easily adapted to solve problems with different scopes.

Abstract. The growing use of agrochemicals added to the harm that contaminated containers cause to the environment and to the health of the population, make it necessary to establish a reverse supply chain for the recovery and correct treatment of empty containers. Current regulations establish that they must be triple-rinsed and sent to collection centers, where containers are consolidated and shipped to treatment/recycling plants. Containers can also be sent to these plants directly. Given this problem, this contribution proposes an MILP multiperiod model to define the optimal configuration and operation of the reverse supply chain network of empty agrochemical containers along a given planning horizon. Provided a superstructure including farms and the location of the potential nodes (collection centers and plastic treatment plants), the model determines which facilities to install and when, their corresponding sizes, as well as how they would operate along the planning horizon. In addition, the model establishes the material flows among the various nodes in each planning period (network topology). The proposed model has been verified by addressing a realistic case study, which has been solved under different scenarios, exhibiting good computational performance. The obtained results allow reaching satisfactory conclusions in relation to model scalability and sensitivity.

Keywords: Reverse Logistics · Supply chain design and planning · Empty agrochemical containers ·Mixed-integer linear programming model

1 Introduction

Current supply chains are not limited to unidirectional product flows from manufactures to consumers. On the contrary, they need to deal with opposite material flows devoted to the reuse, recycling and/or final disposal of products, parts, as well as packaging and empty product containers. Managing these inverse flows confronts companies with novel challenges that need to be analyzed under the umbrella of reverse logistics. It can be defined as the process of planning, implementing and controlling backward flows of raw materials, in process inventory, packaging and fi-

nished goods, from a manufacturing, distribution or use point, to a point of recovery or point of proper disposal [1].

This contribution addresses the design of a reverse supply chain of agrochemical containers. It is intended to collect and thoroughly clean the plastic vessels, once they have been emptied and triple-rinsed, with the aim of recycling/using the plastic, decontaminating the washing water, while minimizing the associated environmental and health risks. The problem of configuring such network along a given planning horizon implies establishing: (i) the number and location of collection centers – intermediate points for collecting containers – , as well as plastic treatment plants to be installed, (ii) the time period in which each facility will be installed and the ones in which it will operate, (iii) the capacities of the various storage and processing facilities, (iv) for each time period, which are the flows of materials between farms, which generate the containers, and the collection/treatment points, as well as the flows between collection centers and plastic treatment plants. This problem is addressed by means of a multi-period MILP (Mixed Integer Linear Programming) model that is able to tackle the challenges previously presented while minimizing the total actual discounted cost of the network.

This contribution is organized as follows. Section 2 contains a brief literature review on the design of reverse supply chains. The mathematical model is presented in Section 3. In Section 4, a realistic case-study, which allows testing the formulation, is described. Computational results and a sensitivity analysis are presented in Section 5. The contribution ends with concluding remarks and a summary of future work.

2 Literature review

Facility location decisions play a critical role in the design of supply chain networks, as pointed out in [2]. This review article presents a comprehensive analysis of several facility location approaches by identifying basic characteristics (number of products, number of periods of the planning horizon, type of network structure, uncertainty consideration, etc.) that models must capture in order to address different kinds of supply chain planning problems that are of practical interest. It considers both the typical node location-allocation decisions and their integration with other decisions that are relevant to problems of optimal design and planning of supply chain networks. This review paper shows that the supply chain configuration and planning problems have increasingly drawn the attention of the scientific community during the last two decades. In addition, sustainability aspects started playing a central role, thus impacting not only on the objectives to be pursued – economic, environmental and social – [3], but also on the reverse flows of materials to be considered [4].

Reverse logistics is defined as the process of planning, implementing and controlling backward flows of materials (raw materials, in-process inventory, packaging and finished goods), from a manufacturing, distribution or use point, to a point of recovery and/or proper disposal. Two main types of reverse logistics design and planning problems can be identified [2]: (i) The ones associated with closed-loop networks, where the reverse network is fully integrated with the forward chain, thus allowing

the simultaneous definition of the optimal distribution and recovery networks, and; (ii) Recovery network problems, i.e. the ones that are limited to recovery and/or disposal activities. Regarding these last ones, [5] proposes a mathematical programming framework that accommodates several characteristics of practical relevance: a multi-period setting, modular capacities, capacity expansion of the facilities, reverse bills of materials, variable operational costs, among other features. Other generic mathematical programming formulations to address reverse network configuration problems were proposed in [3-4]. In particular, [3] presents a multi-objective model that integrates the three dimensions of sustainability: economic, environmental, and social.

Despite the fact that the number of scientific publications related to the reverse logistics domain has been steadily growing, showing the increasing importance of the field due to the environmental awareness of the society, generic models cannot address all the situations that are found in practice yet. Even for the subfield of solid waste management, [6] have pointed out the various specific features that are to be considered, which may need to be further adapted under an extended producer responsibility approach.

Regarding the reverse supply chains of empty agrochemical containers, few contributions have been found. Lagarda-Leyva [7] addressed the reverse supply chain of agrochemical plastic containers associated with Roma tomato production in a Mexican region. The contribution proposed causal conceptual models that allow developing Forrester's dynamic models that, in turn, have been employed to simulate and assess the operation of the system under dynamic conditions within three different scenarios. Recently, [8] reported a preliminary approach to address the design of the reverse network of empty agrochemical containers in a region of Buenos Aires, Argentina. The proposal includes two MILP formulations. The first one is a single period facility location model that allows selecting, out of a set of potential places, the settings of temporary collection centers (CATs) and a main gathering operation site (OP), where the containers are get together. The potential facilities have fixed capacities. In addition, their operation and installation costs are omitted. The modeling of material flows and transportation costs is also very simple since the transportation from farms to collection centers is not taken into account (farms are not part of the problem). The second model, which must be applied to the solution of the first one, addresses the routing problem associated with the movement of empty containers from CATs to the main gathering point.

It can be concluded that the optimal configuration of the reverse supply chain network of empty agrochemical containers is still a challenging problem that deserves attention and will be addressed in the remaining sections of this contribution.

3 Mathematical programming formulation

In this Section a multi-period mixed-integer linear programming (MILP) model for the design of the reverse logistics network previously described is presented.
Given:

- a planning horizon of a certain length,

- the set of farms, each one generating a pre-specified number of empty containers in each period of the planning horizon,
- the superstructure that includes all the potential/existing collection centers and possible/existing plastic treatment plants, as well as the farms – i.e. all the nodes to be considered for the network design – and their interconnections – i.e. the arcs and their associated distance,
- the set of possible discrete sizes of collection centers/treatment plants,
- the sizes of the facilities already installed at the beginning of the planning horizon,
- maximum and minimum storage capacities for a collection center/treatment plant of a given size,
- maximum and minimum processing capacities of each treatment plant size,
- maximum capacity of each type of truck to be used,
- number of periods required by a new facility to start operating,
- installation and fixed operational cost of collection centers/treatment plants,
- variable processing cost of treatment plants,
- transportation cost per unit distance between the different types of nodes.

Determine:

- which collection centers and plastic treatment plants to install, and when to install them,
- capacity of each facility to be built,
- which collection centers and plastic treatment plants to operate along each period of the planning horizon
- container flows between farms and collection centers, farms and treatment plants and collection centers and treatment plants during each planning period.

So as to minimize the total actual discounted cost of the network.

3.1 Model assumptions

It is assumed that: (i) all the model parameters are deterministic, i.e. no uncertainty is considered, (ii) the containers that are generated in a given period must be collected and treated in the same period, (iii) collection centers and plastic treatment plants to be installed are of discrete capacities, (iv) variable operating costs are taken into account only for plastic treatment plants, (v) transportation costs only consider the distance traveled and omit the load of the vehicles.

3.2 Nomenclature

Sets/indices

F/f	farms
J/j	collection centers
P/p	plastic treatment plants

J^i / P^i	subset of transitory centers/treatment plants that are already installed at the beginning of the planning horizon
M/m	set of available sizes of collection centers
N/n	set of available sizes of plastic treatment plants
$T/t, t'$	time periods

Parameters

g_{ft}	number of containers to be generated by farm *f* during period *t*
$d_{fj}/d_{fp}/d_{jp}$	distance between nodes of different types
k_m^{min}/k_n^{min}	minimum capacity of a collection center/treatment plant of size *m/n*
k_m^{max}/k_n^{max}	maximum capacity of a collection center/treatment plant of size *m/n*
nt^j / nt^p	number of time periods required by a new collection center/treatment plant to start operating from the period it is installed
$c^{fj}/c^{fp}/c^{jp}$	transportation cost per distance unit between the different nodes of the network
ir	interest rate
fc_m/fc_n	fixed cost of operation of a collection center/treatment plant of size *m/n*
vc	variable production cost of plastic treatment plants
cc_m^j/cc_n^p	construction cost of a collection center/treatment plant of size *m/n*
ec_n	equipment cost of a treatment plant of size *n*
cap	loading capacity of the trucks that travel between collection centers and treatment plants
nf_{ft}	number of trips required to transport the total generation of containers of farm *f* during period *t*
$nmax$	$max\ (nt^j, nt^p)$. number of periods that must be considered previous of the start of the planning horizon for the installation of facilities

Decision variables

Binary variables

X_{jm}/X_{pn}	equal to one if collection center *j*/treatment plant *p* of size *m/n* is installed
Y_{jt} / Y_{pt}	equal to one if collection center j/treatment plant *p* operates in period *t*
I_{jt}/I_{pt}	equal to one if collection center j/treatment plant *p* is installed in period *t*

Positive variables

$S_{fjt}/S_{fpt}/S_{jpt}$	number of containers sent between nodes of different types in period *t*

3.3 MILP formulation

Using the above definitions, the model is formulated as follows.

$$\text{Min} \quad \sum_{t} \frac{Icc_t + Icp_t + Vcp_t + Ocj_t + Ocp_t + Tc_t^{fj} + Tc_t^{fp} + Tc_t^{jp}}{(1+ir)^{t-1}} \tag{1}$$

$$s.t. \quad g_{ft} = \sum_{\forall j \in J} S_{fjt} + \sum_{\forall p \in P} S_{fpt} \qquad \forall f \in F,\ \forall t \in T > nmax \tag{2}$$

$$\sum_{\forall f \in F} S_{fjt} = \sum_{\forall p \in P} S_{jpt} \qquad \forall j \in J, \forall t \in T > nmax \tag{3}$$

$$\sum_{\forall t,\ t' + nt^j \le t} I_{jt'} \ge Y_{jt} \qquad \forall j \in J,\ j \notin J^i, \forall t \in T \tag{4}$$

$$\sum_{\forall t,\ t' + nt^p \le t} I_{pt'} \ge Y_{pt} \qquad \forall p \in P,\ p \notin P^i, \forall t \in T \tag{5}$$

$$\sum_{\forall m \in M} X_{jm} = \sum_{\forall t \in T} I_{jt} \qquad \forall j \in J,\ j \notin J^i \tag{6}$$

$$\sum_{\forall n \in N} X_{pn} = \sum_{\forall t \in T} I_{pt} \qquad \forall p \in P,\ p \notin P^i \tag{7}$$

$$\sum_{\forall m \in M} X_{jm} \le 1 \qquad \forall j \in J \tag{8}$$

$$\sum_{\forall n \in N} X_{pn} \le 1 \qquad \forall p \in P \tag{9}$$

$$\sum_{\forall f \in F} S_{fjt} \le k_{m=max}^{max}\ Y_{jt} \qquad \forall j \in J, \forall t \in T,\ t > nmax \tag{10}$$

$$\sum_{\forall f \in F} S_{fjt} \le \sum_{\forall m \in M} k_m^{max}\ X_{jm} \qquad \forall j \in J, \forall t \in T,\ t > nmax \tag{11}$$

$$\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \le k_{n=max}^{max}\ Y_{pt} \qquad \forall p \in P, \forall t \in T,\ t > nmax \tag{12}$$

$$\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \le \sum_{\forall n \in N} k_n^{max}\ X_{pn} \qquad \forall p \in P, \forall t \in T,\ t > nmax \tag{13}$$

$$\sum_{\forall f \in F} S_{fjt} \ge k_{m=1}^{min}\ Y_{jt} + \sum_{\forall m \in M,\ m>1} (k_m^{min} - k_{m=1}^{min})(Y_{jt} + X_{jm} - 1) \qquad \forall j \in J, \forall t \in T,\ t > nmax \tag{14}$$

$$\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \ge k_{n=1}^{min}\ Y_{pt} + \sum_{\forall n \in N,\ n>1} (k_n^{min} - k_{n=1}^{min})(Y_{pt} + X_{pn} - 1) \qquad \forall p \in P, \forall t \in T,\ t > nmax \tag{15}$$

$$Icc_t = \sum_{\forall j \in J,\ j \notin J^i} \sum_{\forall m \in M} cc_m^j \left(I_{jt} + X_{jm} - 1\right) \qquad \forall t \in T \tag{16}$$

$$Icp_t = \sum_{\forall p \in P,\ p \notin P^i} \sum_{\forall n \in N} (cc_n^p + ec_n) \left(I_{pt} + X_{pn} - 1\right) \qquad \forall t \in T \tag{17}$$

$$Vcp_t = \sum_{\forall p \in P} vc \left(\sum_{\forall f \in F} S_{fpt} + \sum_{\forall j \in J} S_{jpt} \right) \qquad \forall t \in T \tag{18}$$

$$Ocj_t = \sum_{\forall j \in J} \sum_{\forall m \in M} fc_m \, (Y_{jt} + X_{jm} - 1) \qquad \forall t \in T \qquad (19)$$

$$Ocp_t = \sum_{\forall p \in P} \sum_{\forall n \in N} fc_n \, (Y_{pt} + X_{pn} - 1) \qquad \forall t \in T \qquad (20)$$

$$Tc^{fj}{}_t = \sum_{\forall f \in F} \sum_{\forall j \in J} c^{fj} \; 2 \; d_{fj} \; \frac{S_{fjt}}{g_{ft}} \; nf_{ft} \qquad \forall t \in T \qquad (21)$$

$$Tc^{fp}{}_t = \sum_{\forall f \in F} \sum_{\forall p \in P} c^{fp} \; 2 \; d_{fp} \; \frac{S_{fpt}}{g_{ft}} \; nf_{ft} \qquad \forall t \in T \qquad (22)$$

$$Tc^{jp}{}_t = \sum_{\forall j \in J} \sum_{\forall p \in P} c^{jp} \; 2 \; d_{jp} \; 1.2 \; \frac{S_{fpt}}{cap} \qquad \forall t \in T \qquad (23)$$

The objective function, given by expression (1), comprises the different costs involved in the design and operation of the logistics network throughout the planning horizon: (i) installation costs of collection centers and treatment plants, (ii) variable costs of handling empty containers in treatment plants, (iii) fixed operation costs of facilities, and (iv) transportation costs between the different nodes of the network. In order to determine how much future projected cash flows are worth at present, these cost components are affected by an annual interest rate, according to the multi-period total discounted cost formula given by (1). The model includes constraints (2)-(23).

Eq. (2) prescribes that all the containers generated by a farm in a certain period, must be sent to a collection center and/or to a treatment plant in the same planning period. Similarly, Eq. (3) states that all the containers that are received by a collection center in a given period must be sent to a plastic treatment plant in the same period.

Expression (4) assures that a collection center can operate in a certain period only if it has been installed in a previous one. Expression (5) forces treatment plants to obey the same restriction. Eq. (6) states that if a collection center is installed in one of the periods, it must adopt one of the *m* available sizes. In a similar way, Eq. (7) prescribes that if a plastic treatment plant is installed in one of the periods, it must be of one of the *n* available sizes. Expressions (8) and (9) force that every collection center/treatment plant that is installed should adopt just one of the available sizes.

According to inequalities (10) and (11), the number of containers sent to a given collection center in each period, should not overpass the maximum storage capacity corresponding to the installed size. The maximum capacity of each treatment plant to be built is captured by means of expressions (12) and (13). They have the same rationale as (10) and (11). Following analogous ideas, the minimum capacity of each collection center and plastic treatment plant to be installed is given by expressions (14) and (15), respectively.

Expressions (16) - (23) capture the different cost terms participating in the objective function. Eq. (16) defines the investment cost of new collection centers in each period, Icc_t. Similarly, Eq. (17) captures the investment cost of new treatment plants in each period. It takes into account both the construction cost and the equipment cost associated with the size of the plant to be installed. It should be noted that these costs are calculated by applying scale economies. Variable costs per period are only consi-

dered for plastic treatment plants, as shown in Eq. (18). They take into account unit processing cost and the total number of containers sent to each plant in each period. The fixed operation cost associated with collection centers in each period, Ocj_t, is given by Eq. (19). The fc_m cost parameter depends on the adopted size m. Similarly, Eq. (20) establishes the fixed operation cost of treatment plants in each period, Ocp_t. The fc_n cost depends on the size n that is adopted for each treatment plant. The transportation costs from farms to collection centers for each one of the planning periods is captured by Eq. (21). As seen, round trips are taken into account by multiplying the transportation cost per distance unit from farm f to collection center j, c^{fj}, by twice the distance between these nodes. In turn, this is multiplied by the proportion of the number of trips required to transport the total generation of containers of the farm that are just sent to the collection center. It should be noted that nf_{ft} is calculated considering 1.5 times the actual number of trips that would be required if the complete vehicle capacity would have been employed. This assumption relies on the fact that most of the trips are made with less than the maximum allowed load. The proportion is calculated by dividing the number of containers sent from each farm to each collection center in a given period, by the container generation of the farm in such a period. The transportation cost from farms to treatment plants, for each planning period, is captured by Eq. (22) in the same way the transportation cost between farms and collection centers has been estimated. Finally, the transportation cost from collection centers to treatment plants, for each planning period, is calculated by Eq. (23). In this case, it is considered 1.2 times the total number of required trips, since a better container load consolidation can be carried out.

4 Case study description

The MILP model presented in the previous section has been implemented to establish the reverse logistic network configurations and operation policies associated with several scenarios of a realistic case study. Such case study corresponds to the handling and treatment of empty agrochemical containers in three northern departments of the Santa Fe province, Argentina. This province has one of the most significant agricultural productions in the country. Consequently, it has one of the largest generations of empty agrochemical containers, which are used to control unwanted pests and weeds of crops. As already presented, this reverse supply chain comprises three types of nodes: farms, transitory collection centers, and treatment plants. In these last facilities the plastic is thoroughly cleaned and subsequently pelletized. In addition, the water that is employed in the process is decontaminated before it is recycled, so as to minimize the use of fresh water. Treatment plants can also act as collection centers.

The operation of this recovery system is regulated by national law 27279, which is implemented in a very incipient way in Argentina. This law prescribes that empty agrochemicals containers must be triple-rinsed in farms, which are also responsible for their shipment to collection centers and/or treatment plants. Unfortunately, the system does not work well in practice, farmers fail to meet their obligations and there are not enough collection centers installed - which causes both high transportation

costs and a large carbon footprint. Furthermore, government agencies do not have tools to assess how the law can be satisfactorily complied with, from an economic and environmental perspective, by establishing a proper recovery network. All these elements allow concluding that the problem deserves the attention of the scientific community.

Since this case study considers strategic and tactical decisions, it will be simplified in order to reduce the dimensionality of the resulting mathematical models. Therefore, aggregated farms of approximately 500 hectares will be defined by grouping neighboring farms and assigning to them a fictitious location and an aggregate number of containers. Though it is a simplification, this assumption is pretty common in supply chain strategic decision making problems, which generally consider aggregated products, aggregated customers, or as in this case aggregated farms. The explicit consideration of farms is one of the main differences between the proposed approach and the first model reported in [8].

The number of containers generated per year by each farm has been obtained as a random parameter whose value lies between the minimum and maximum amounts of agrochemicals that are annually applied per hectare, multiplied by the number of hectares where agrochemicals are employed. These random values were also affected by a slight increasing tendency in order to represent that in this region open field livestock activities are being replaced by agricultural ones. The location of potential collection centers that has been considered coincides with the one of municipalities and counties located in the region of interest. With regard to the transportation of empty containers, according to current regulations in Argentina, the vehicles employed to make movements from farms to collection centers and/or treatment plants, should be pick-up vans, having a capacity limit that has been considered in the model. On the other hand, the transportation from collection centers to treatment plants is done by means of trailer trucks having a much greater capacity and lower transportation costs.

Initially, a simple base case has been tackled. It takes into account a superstructure composed of 300 farms, 20 potential collection centers, 8 potential treatment plants and no existing facilities that are already installed. Two different capacity modules for collection centers and treatment plants – i.e. two discrete sizes for each type of facility – have been allowed for. The planning horizon considers 6 years of operation of the collection-treatment system, plus an initial year for the installation of the first facilities. Thus, during the initial year the system does not operate, but the required facilities are being built. This base case has been further extended to test the scalability of the model and its sensitivity to changes in the number of farms, the number of potential collection centers/treatment plants, as well as the length of the planning horizon.

5 Computational results

The model has been implemented in GAMS 23.6, running on an Intel Core i8 computer, with 3.4 GHz, 8 GB of RAM, and using CPLEX as a solver. Initially, the model – expressions (1) to (23) – was solved to assess its computational performance.

The optimal solution corresponding to the base case was reached in 3283s of CPU. Since this is the simplest case of those evaluated, and the CPU time was considerably high, a two-step relaxation approach was proposed to increase the computational efficiency. The proposed approach works as follows. In the first stage, the model composed of expressions (1) to (23) is solved as a linear formulation, relaxing all the binary variables. In a second stage, the original model is solved, but variables I_{jt} and I_{pt} are fixed to zero in those cases having such value in the relaxed model solution. The remaining binary variables – those having a value greater than zero in the relaxed model solution – are given freedom to take either one or zero values. This relaxation approach proved to be quite effective in all the examples that have been solved.

Fig. 1 depicts the optimal solution of the base case, which was obtained in 1565 s. Thus, the same solution was reached with a reduction of 52.33% in the CPU time. During the initial year seven collection centers (red dots) and two treatment plants (black squares) are installed, and they operate along the whole planning horizon. Two collection centers are of the smallest size, with a maximum capacity of 5,000 containers per period. The remaining five correspond to the larger size, being able to handle up to 10,000 containers per period. One small and one large treatment plant are installed, with a maximum capacity of 60,000 and 100,000 empty containers, respectively.

Fig. 1. Optimal solution for the base case problem. Seven collection centers (red dots) and two treatment plants (black squares) are installed previous to the beginning of the planning horizon.

In order to analyze the model scalability and to test its response to changing conditions – i.e. to make a simple sensitivity analysis –, several additional scenarios have been solved using different data sets. Tables 1 and 2 summarize some of the scenarios that have been addressed. All the examples were solved to optimality if the optimal solution was found within 10000 s. Otherwise, a 5% gap was fixed as the stopping criterion, with the exception of one case in which a 10% gap was adopted. The sizes of the resulting models, as well as the computational results, are presented in Table 3. This table reports the statistics corresponding to the relaxation methodology. However, it should be remarked that in all the cases, the same solutions have been obtained when the speed-up approach is omitted, i.e. when solving the regular model. The following paragraphs present an analysis of the 10 examples that have been tackled.

Scenario 1 duplicates the number of farms with respect to the base case, but keeps constant the number of potential collection centers and plastic treatment plants. As

shown in Table 3, the number of binary decision variables does not increase, but the continuous ones almost duplicate, as well as the number of constraints. No optimal solution was obtained within 10000 s, but a solution with a 5% of relative gap was reached in 3099 s. The attained solution comprises the same number of collection centers as the base case solution, but has two more treatment plants. All the installed collection centers are of the large size. Regarding treatment plants, two small and two large are selected. In this way the capacity of the network is increased in order to serve a greater number of farms. All facilities are installed during the first period and operate along the whole planning horizon.

Table 1. Summary of some of the different dimension analyzed scenarios.

	Farms	Possible Collection Centers	Possible Treatment Plants	Horizon length
Base Case	300	20	8	6
Scen. 1	600	20	8	6
Scen. 2	300	20	8	12
Scen. 3	300	20	16	6
Scen. 4	300	40	8	6

Table 2. Summary of some of the different analyzed scenarios disturbing parameters.

	Disturbed parameter	Direction and intensity of disturbance
Scen. 5	Containers generation	50% reduction in period 3
Scen, 6	Containers generation	Generalized gradual decrease
Scen. 7	Transportation costs	10% increase
Scen. 8	Transportation costs	20% increase
Scen. 9	Installation costs	10% increase
Scen. 10	Installation costs	20% increase

Table 3. Computational results corresponding to the different scenarios.

	Total Variables	Binary variables	Total constraints	Objective Function	CPU s	Relative Gap
Base Case	52,335	392	2,855	1,582,355.44	1,565	0,00
Scen. 1	119,848	392	5,184	2,850,718.12	3,099	0,05
Scen. 2	113,326	728	6,558	1,940,178.00	215*	0,00
Scen. 2	113,326	728	6,558	1,940,178.00	9,758#	0,10
Scen. 3	79,320	504	3,832	1,582,355.44	4,403	0,00
Scen. 4	104,908	672	4,484	1,511,971.51	9,715	0,05
Scen. 5	52,335	784	2,855	1,559,379.32	3,489	0,00
Scen. 6	52,335	784	2,855	1,462,987.45	1,634	0,00
Scen. 7	52,335	784	2,855	1,542,416.85	1,258	0,00
Scen. 8	52,335	784	2,855	1,571,170.39	1,558	0,00
Scen. 9	52,335	784	2,855	1,618,496.74	1,308	0,00
Scen. 10	52,335	784	2,855	1,723,330.16	2,489	0,00

*Base Case solution taken for the five initial periods

No solution given to the solver, 10 periods considered all at once.

Scenario 2 takes into account the same superstructure as the base case, but doubles the length of the planning horizon. This leads to duplication in the number of continuous and binary variables, as well as the number of constraints. This more challenging scenario has been tackled with two different solution approaches. The first one considers the base case solution as given, and extends the horizon to evaluate potential new facilities. In this case, the optimal solution has been found in only 215 s. The second approach does not resort to any initial network and the 10 periods are taken into account from the beginning. A solution with a gap of 10% has been reached in 9758 s. The same solution (see Fig. 2) is obtained in both cases. It comprises twelve facilities: 9 collection centers and 3 treatment plants, all of which are installed during the initial period, with the exception of one treatment plant, which is built in period 5. The sizes of the various facilities are summarized in Table 4.

A comparison of the solutions corresponding to the base case and scenario 2 shows that the effect of having a longer planning horizon is to increase the investment in the installation of facilities with the aim of reducing transportation costs, that otherwise would have been much higher. In fact, the base case solution has as its main cost components the installation and transportation ones, with a participation of 56.6 % and 18.17%, respectively. In the case of scenario 2 solution, the participation of these components changes to 52.99% and 20.98%, respectively, despite the fact that three more facilities are installed.

Fig. 2. Optimal solution corresponding to scenario 2. Nine collection center (red dots) and three treatment plants (black squares) are installed previous to the beginning of the planning horizon.

Table 4. Facilities to be installed in each one of the different scenarios.

	Collection centers	Treatment plants	Size of collection centers	Size of treatment plants
Base Case	7	2	2 small, 5 large	1 small, 1 large
Scen. 1	7	4	all large	2 small, 2 large
Scen. 2	9	3	5 small, 4 large	2 small, 1 large
Scen. 3	7	2	2 small, 5 large	1 small, 1 large
Scen. 4	12	2	9 small, 3 large	1 small, 1 large
Scen. 5	7	2	2 small, 5 large	1 small, 1 large
Scen. 6	6	2	1 small, 5 large	1 small, 1 large
Scen. 7	7	2	2 small, 5 large	1 small, 1 large
Scen. 8	7	2	2 small, 5 large	1 small, 1 large
Scen. 9	7	2	2 small, 5 large	1 small, 1 large
Scen. 10	7	2	2 small, 5 large	1 small, 1 large

Scenario 3 duplicates the number of potential treatment plants in relation to all the previous cases, but keeps constant the number of farms, collection centers and the length of the planning horizon with respect to the base case. The 16 possible treatment plants include the 8 ones associated with the base case. Provided the model has a bigger superstructure (504 versus 392 binary variables) with respect to the base case, it has the opportunity of finding a solution with a lower objective function value, or at least to reach the same solution as in the base case. The same solution as the base case one was reached in 4403 s, which indicates that in this case the new potential treatment plants do not lead to a solution improvement.

Along the same ideas, scenario 4 duplicates the number of potential collection centers in relation to all the previous cases, but keeps constant the number of farms, treatment plants and the length of the planning horizon with respect to the base case. As shown in Table 3, no optimal solution was obtained within 10000 s, but a solution having a 5% of relative gap has been reached in 9715 s. Given that the 40 potential collection centers include the 20 ones that correspond to the base case, a solution equivalent to the base case one, or better, was expected. In this case, the additional potential collection centers lead to an improvement in the base case solution. The new network comprises 5 extra collection centers, reducing the total discounted cost of the network due to savings in the transportation costs. In addition, the 5% gap indicates that further improvements can be obtained. Scenarios 3 and 4 allow concluding that the greater the number of potential nodes included in the superstructure, the greater the chances of obtaining good quality solutions. As expected, the increase in the number of binary variables demands an additional computational effort.

Scenarios 5 to 10 take into account the same superstructure as in the base case, but propose disturbances in different parameters to test the sensibility of the model to the changes. Scenarios 5 and 6 perturb the generation of empty containers from farms. In the first case, the generation of the base case is reduced by 50% in period 3, simulating an epoch with a reduced usage of agrochemicals due to changes in climatic conditions (drought). On the other hand, scenario 6 considers a gradual decrease in the generation of empty containers, in the same proportion for every farm, starting from period 3 up to the end of the planning horizon.

The optimal solution corresponding to scenario 5 was reached in 3489 s of CPU. It has the same facilities (see Fig. 1) identified in the base case solution. However, in this perturbed scenario two of the collection centers do not operate in period 3. The facilities that work in this period are the ones shown in Fig. 3. In turn, the optimal solution associated with scenario 6 was reached in 1634 s of CPU. It comprises six collection centers, one less than the base case solution. The reduction of facilities is due to the fact that fewer empty containers are generated along the planning horizon.

Scenarios 7 and 8 disturb the transportation cost, by proposing an increase of 10% and 20%, respectively. The structure of the solutions that have been obtained in both cases is the same as the one reached for the base case. Nevertheless, the total discounted cost of the network is higher due to the rise in transportation costs. These results show that the increments in the transportation costs are not yet enough to produce a modification in the network topology.

Finally, scenarios 9 and 10 disturb the installation costs of both types of facilities, by proposing an increase of 10% and 20%, as compared to the ones of the base case,

respectively. The optimal solution corresponding to scenario 9 was reached in 1308 s of CPU, whereas the one of scenario 10 required 2489 s of CPU. In both cases, the structure of the solution that was obtained is the same as the one associated with the base case. As expected, the total cost of the attained networks exhibit an increase, due to the rise in the installation costs of the facilities. Similarly to what happened in scenarios 7 and 8, the augmentations in the installation costs are not yet enough to produce a modification in the number and capacity of those facilities to be installed. As already presented, the base case solution has as its main cost components the installation and transportation ones, with a participation of 56.6% and 18.17%, respectively. In turn, the solution of scenario 9 has the following cost participation: 60.33% corresponding to installation costs and 17.8% to transportation ones. These percentages change to 61.4% and 16.7% in the case of the solution of scenario 10.

Fig. 3. Solution associated with scenario 6, showing the facilities that operate during period 3: Five collection centers (red dots) and two treatment plants (black squares).

6 Concluding remarks and future work

An MILP model for a multi-period reverse logistics network design problem has been presented. It takes into account several features that become relevant in supply chain configuration problems, such as: multi-period consideration, a three echelon network, discrete sizes for two facility types, minimum and maximum capacities for each of the available sizes of such facilities, as well as facilities that may have been already installed. In addition, the model considers variable costs per unit processed in the treatment plants, fixed operational costs and installation costs for all the available sizes of each facility type. Transportation costs only consider the distance traveled and omit the load of the vehicles, assuming that most of the trips are made with less than the maximum allowed load.

In order to reduce the computational load, a relaxation approach has been proposed. It rendered significant reductions in the CPU times without degrading, in any case, the quality of the attained solutions.

The model has been tested under various scenarios to analyze scalability and sensitivity issues. The obtained results have been satisfactory. Nevertheless, further testing will be done in the future to better study these aspects. For instance, a time horizon

with periods of shorter duration and a superstructure with more nodes will be tackled. In addition, the solutions will be evaluated under more demanding conditions of change in the model parameters. This would allow to better understand the tradeoffs between installation and transportation costs. Finally, the incorporation of environmental and social objectives, in addition to the economic ones, will be pursued in the future. This will naturally lead to a multi-objective formulation.

Prefacio

Simposio Industrial ICPR-Americas 2020

Este volumen incluye los artículos presentados en el SIMPOSIO INDUSTRIAL de la "*Xth International Conference of Production Research-Americas*" (ICPR-Américas 2020), realizado en forma virtual en Bahía Blanca, Argentina del 9 al 11 de diciembre de 2020. Este Simposio fue organizado por un comité organizador local de la ciudad de Bahía Blanca y fue auspiciado por la *International Foundation of Production Research* (IFPR). El Simposio Industrial fue un evento complementario del ICPR-Americas destinado a miembros de la industria. En el mismo se presentaron y expusieron trabajos de índole práctica, referidos a las problemáticas en las que ellos mismos participan y los proyectos mediante los cuales abordan y resuelven dichos obstáculos. Los miembros de la industria que participaron del Simposio presentaron especialmente:

- Los problemas con que deben lidiar en la práctica cotidiana.
- El abordaje de los mismos a partir de proyectos de mejora e innovación que hayan implementado o estén implementando.

Los/as autores/as del Simposio Industrial participaron de la conferencia internacional, al igual que los/as autores/as del Congreso Académico. La audiencia y participación durante la presentación de los trabajos del Simposio Industrial contó con amplia asistencia de parte de los autores académicos, dando lugar a un debate que enriqueció recíprocamente a todos los participantes. En el acto de Apertura, los/as autores/as del Simposio Industrial recibieron las palabras del Prof. Luis Quezada de la Universidad de Santiago de Chile, presidente de IFPR. El desarrollo del Simposio Industrial superó ampliamente las expectativas, al contar con 17 trabajos presentados y expuestos por miembros directos de empresas del medio local, regional e incluso con participación de empresas extranjeras. Los trabajos recibidos fueron evaluados y analizados por los miembros de los distintos comités. Por su parte, el comité organizador del Simposio se encargó de toda la organización del evento, desde la concepción y estructuración del mismo -este Simposio fue la primera edición del mismo en el marco del ICPR-Americas-, la difusión, la gestión de los recursos y su administración para hacer posible el evento. También fueron los encargados de la edición de esta parte del Proceeding de ICPR-Americas 2020, titulada: "Simposio Industrial ICPR-Americas 2020".

Finalmente, sólo nos resta agradecer a todos/as los/as participantes, ya que confiaron en la organización de este evento para asistir y compartir sus conocimientos. Y también agradecer a los Sponsors, especialmente a la Universidad Nacional del Sur, en particular a los Departamentos de Ingeniería y Matemática, así como a la Secretaría General de Ciencia y Tecnología, por el apoyo brindado para la realización del evento.

Índice de Satisfacción de Proveedores

Fernando Bono, Matías Sofía

TGS, Bahía Blanca, 8000, Argentina

fernando_bono@TGS.com.ar

Reseña

Transportadora de Gas del Sur S.A. (TGS) es una empresa argentina, que nació en 1992. La compañía realiza 4 actividades principales:

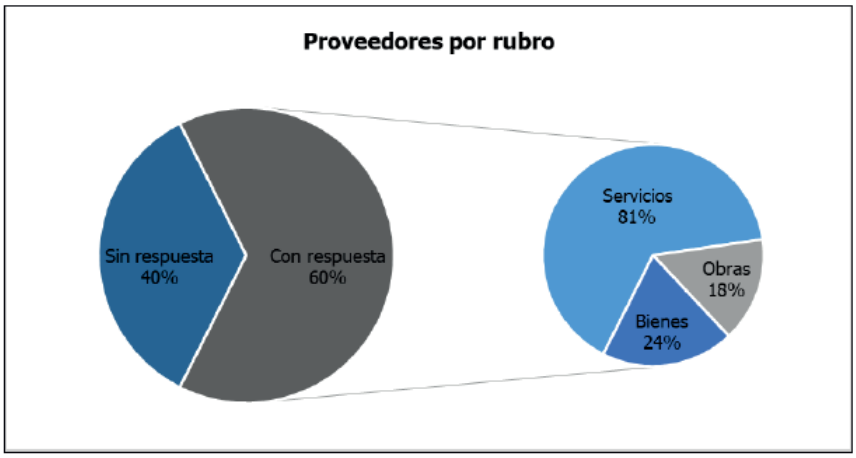
- Transporte de gas natural: es la compañía más importante de Latinoamérica, opera con eficiencia y calidad más de 9.200 km de gasoductos propios, brinda un servicio público desde el sur y oeste de Argentina hacia los centros urbanos. Transporta más del 60% del gas consumido por los argentinos.
- Midstream: Desarrolla servicios a las empresas productoras de petróleo y gas natural en la provincia del Neuquén. En 2019, finalizó la construcción de un gasoducto y una planta de acondicionamiento en Tratayén, Vaca Muerta, que permite llevar el gas de la cuenca a los gasoductos troncales, transformándose en el primer midstreamer de Vaca Muerta.
- Telecomunicaciones: A través de su empresa, Telcosur, brinda servicios de telecomunicaciones en las regiones productivas más importantes del sur y oeste del país, pero también a nivel regional.
- Producción de líquidos del gas natural: en la ciudad de Bahía Blanca, realiza el procesamiento, almacenaje y despacho de butano, propano, etano y gasolina, a través del Complejo Gral. Cerri y la Planta Galván, desde donde se hace el despacho de líquidos a través de camiones y buques.

Para realizar estas actividades, TGS cuenta con 1.100 colaboradores, ubicados en oficinas administrativas, 33 plantas compresoras en las 7 provincias donde desarrolla sus actividades, 3 plantas de acondicionamiento en Neuquén y 2 instalaciones en Bahía Blanca.

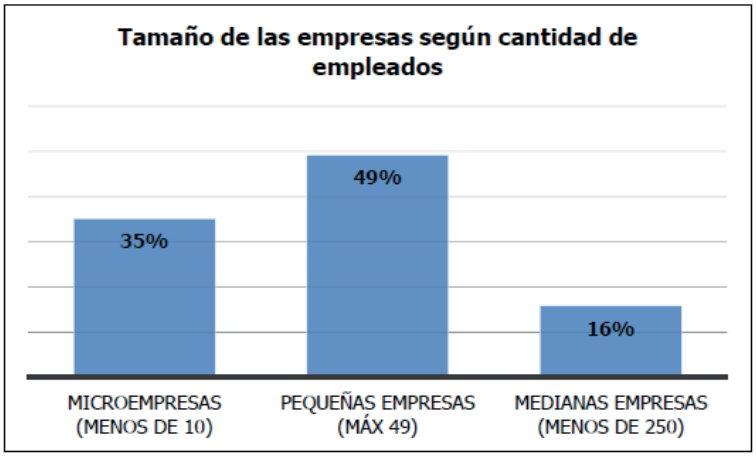
Posee 9.231 km de gasoducto con una capacidad firme de transporte de 85 millones de metros cúbicos/día, con 780.000 HP de potencia instalada.

Su capacidad de procesamiento es de 47 millones de metros cúbicos/día, lo cual hace que sea el segundo procesador de gas natural en la Argentina.

Problemática detectada



TGS se relaciona con una importante cartera de proveedores y contratistas. En su gran mayoría, empresas pymes de servicios, de fabricación y venta de repuestos, e insumos varios. Sin embargo, con el objetivo de atender las necesidades de sus proveedores y contratistas, TGS necesitaba una herramienta que le permitiera fortalecer sus vínculos comerciales. Realizaban consultas directas, pero necesitaba establecer un criterio metodológico de evaluación y mejora continua.



Solución implementada

TGS, en alianza con la UIBB, a través de su Centro de Estudios Económicos, diseñaron un Índice de Satisfacción de Proveedores, que permita medir el grado de satisfacción de los proveedores y aplicar medidas de mejora continua.

El primer paso, consistió en organizar una base de información de proveedores con el objetivo de actualizar los datos de la empresa.

Luego, como prueba piloto, se tomaron los 100 proveedores más importantes de la ciudad de Bahía Blanca y la región y se los dividió en tres grandes grupos: Servicios, Obras y Bienes.

Dichos proveedores debieron responder un cuestionario online, donde se consultó por los siguientes atributos:

- Comunicación: se evaluó la calidad de la comunicación.
- Procesos: los proveedores con acceso a planta evaluaron los procedimientos de la empresa.
- Atención y asesoramiento: la calidad de atención y asesoramiento.
- Resolución de problemas: respecto a la facilidad de resolución de problemas.
- Ejecución: desarrollo de los trabajos en la planta industrial.
- Proceso de pago: fluidez del proceso administrativo.
- Desarrollo de proveedores: se consultó respecto al rol de TGS y la contribución al desarrollo de la cadena de valor.

Para cada atributo, se utilizó una escala de valoración numérica desde el valor 1 (Muy Insatisfecho) al valor 5 (Muy Satisfecho). Un primer procesamiento de las respuestas, permitió obtener un grado de satisfacción por cada atributo relevado.

Posteriormente, se procedió a cruzar las variables con el objetivo de maximizar el análisis. De esta manera, se visualizará el grado de satisfacción, pero vinculando las respuestas, detectando y agrupando las distintas opiniones.

Los resultados de cada atributo se cruzaron con el rubro, la antigüedad de la empresa y el vínculo con TGS, el tamaño de la empresa y el área de TGS.

Este análisis, permite identificar las fortalezas y oportunidades en la relación con proveedores y contratistas y sus características, mejorando el vínculo comercial.

Finalmente, se calculó el Índice de Satisfacción de los Proveedores de TGS. El procedimiento consistió en tres etapas:

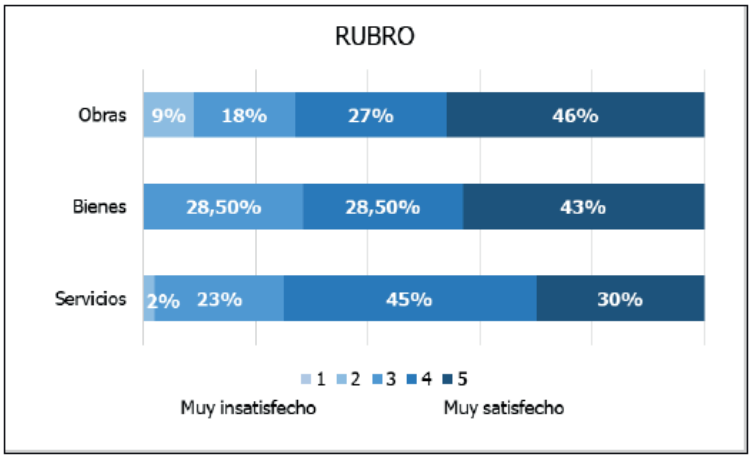
a) Selección de preguntas: consistió en elegir, de cada sección del cuestionario, aquellas preguntas consideradas claves para monitorear el

índice, es decir, cuya respuesta fuera fundamental para saber si mejora o no la satisfacción de los proveedores.

b) Ponderación de secciones y preguntas: consistió en darles un peso relativo tanto a cada sección del cuestionario como a las preguntas elegidas dentro de ellas, a fin de resaltar las más importantes y minimizar las superfluas en el cálculo del índice.

c) Cálculo y obtención del resultado: consistió en una operación matemática sencilla denominada suma ponderada, de acuerdo a las preguntas elegidas en a) y ponderadas en b).

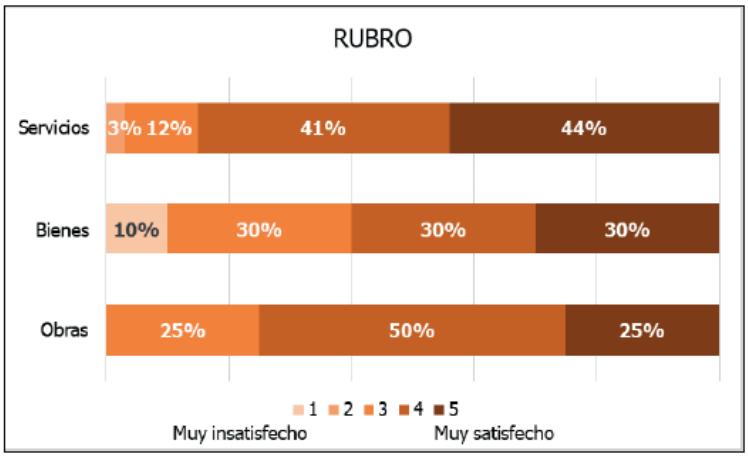
Resultados obtenidos:



El cálculo de la línea de base del Índice de Satisfacción de Proveedores de TGS realizado en el mes de abril del año 2019 arrojó un valor de referencia de 209,4 puntos. La medición periódica del índice, permitirá monitorear si las acciones correctivas implementadas por la empresa tienen efectos positivos, negativos o neutros.

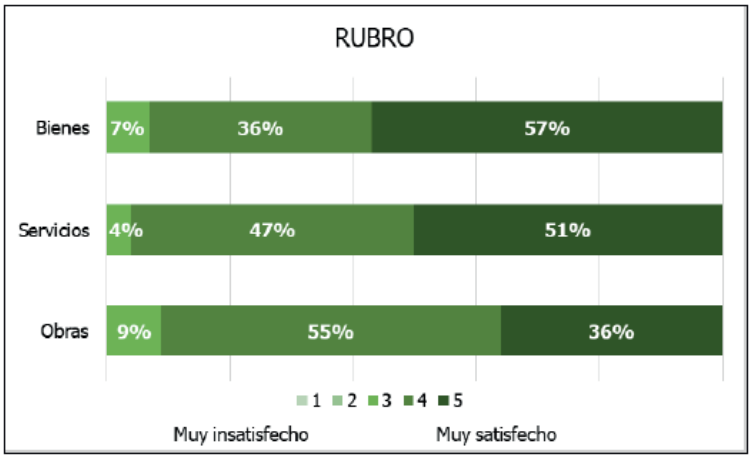
A continuación, se presentan los principales resultados del análisis de cruce de variables:

EJES	CLASIFICACIÓN
Rubro	Bienes Obras Servicios
Antigüedad de la empresa	Mayor a 10 años Entre 6 y 10 años Menor a 5 años
Antigüedad como proveedor	Mayor a 10 años Entre 6 y 10 años Menor a 5 años
Tamaño de la empresa	Medianas empresas (menos de 250) Pequeñas empresas (máx. 49) Microempresas (menos de 10)
Área	Mantenimiento Ingeniería y Obras Ss. generales Seguridad y Medio Ambiente Otro Productos Laboratorio Comunicaciones Vigilancia Servicio Operativo



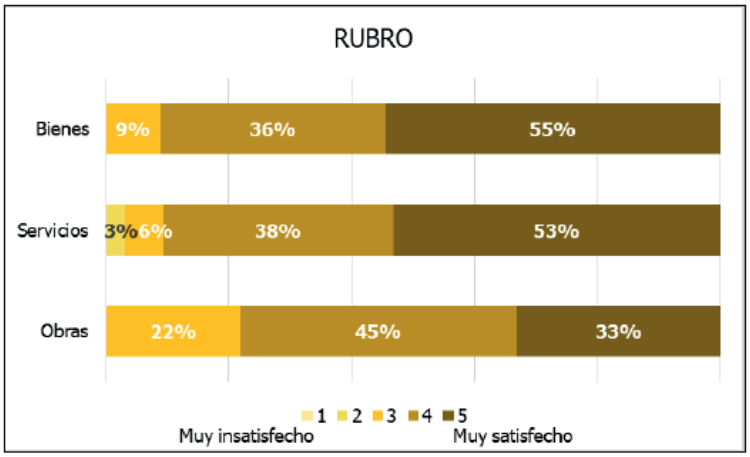
Comunicación

Grado de satisfacción respecto a la experiencia de alta como proveedor de TGS.



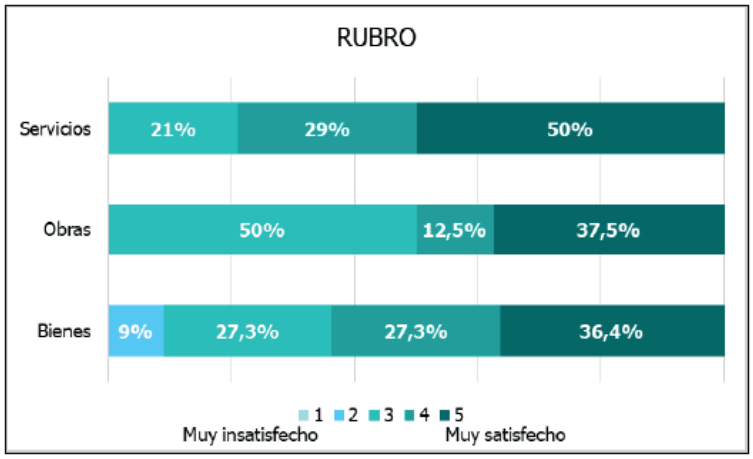
Procesos

Grado de satisfacción con el proceso de acceso al lugar del trabajo en la planta.



Atención y asesoramiento:

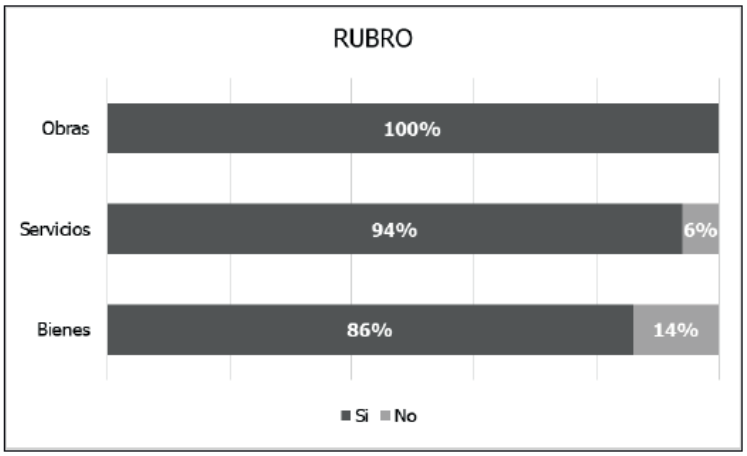
Grado de satisfacción con la calidad profesional del personal de TGS.



Ejecución:

Grado de satisfacción con las condiciones de seguridad que brindaron al personal durante la ejecución de los trabajos.

Proceso de pago:



Utilización y grado de satisfacción del nuevo portal de carga y pago de factura.

Desarrollo de proveedores:

Es un dato significativo: la mayoría de las empresas afirma haber tenido un crecimiento a partir de su relacionamiento con TGS. Esta afirmación proviene del 100% de los proveedores para el caso del rubro "Obras", las empresas entre "6 y 10 años" de antigüedad, las Microempresas y las áreas Servicio Operativo, Vigilancia, Comunicaciones, Laboratorio y Servicios generales.

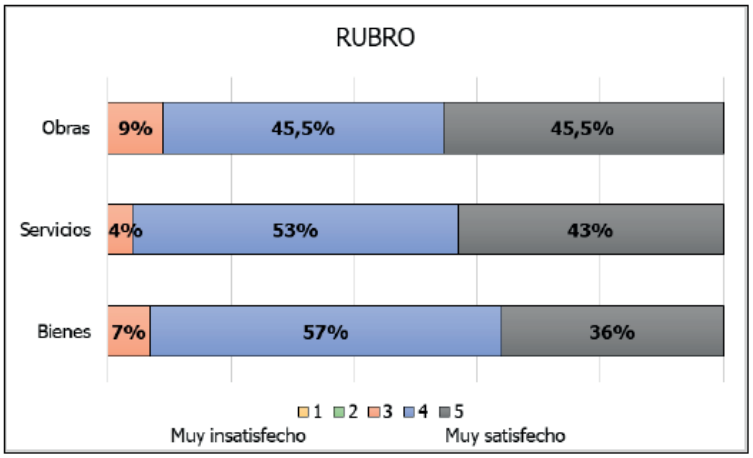


TABLA 1. Crecimiento de la empresa a partir del relacionamiento con TGS.

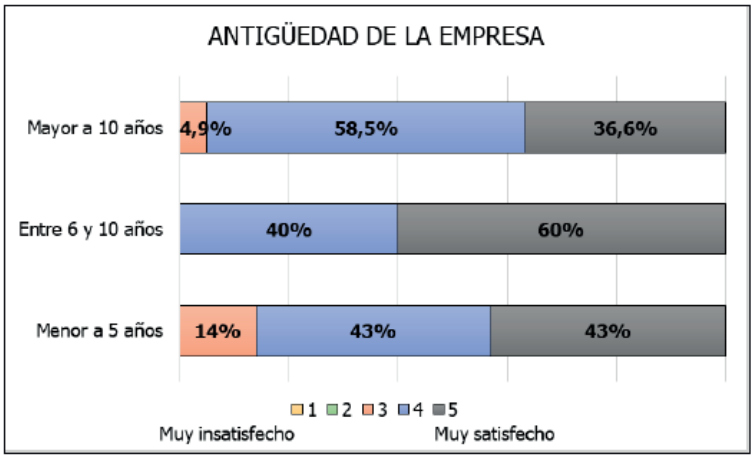
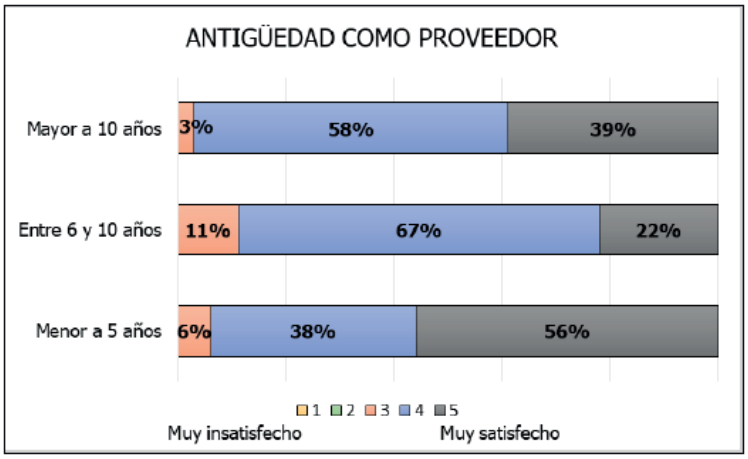
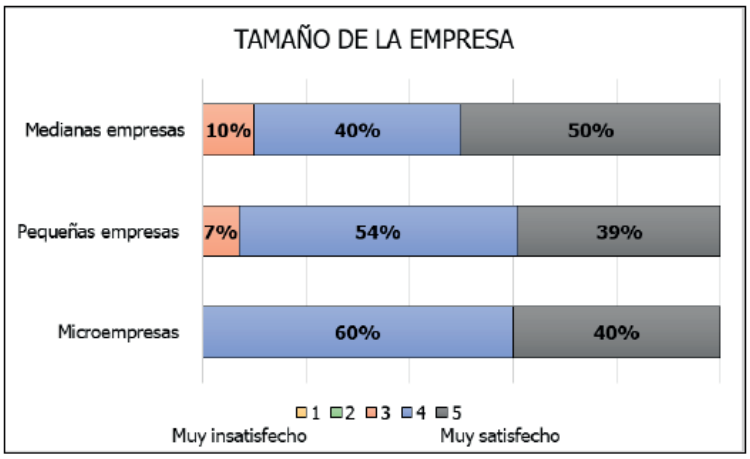




Satisfacción general:



Respecto de la satisfacción general de los proveedores, se puede destacar que no hay calificaciones para la sección más baja de la escala (niveles 1 y 2). Los mayores

porcentajes se encuentran en los niveles 4 y 5, lo que es algo muy positivo para la empresa, ya que independientemente de los inconvenientes específicos los proveedores se muestran satisfechos con su relación comercial.

Comentarios finales:

El caso analizado permitió conocer la vinculación entre una gran empresa (TGS), sus pymes proveedoras y la Unión Industrial. Sin dudas, el Índice de Satisfacción de los Proveedores de TGS tiene aspectos positivos, desde su diseño, por parte del Centro de Estudios Económicos de la UIBB, hasta su análisis en el equipo de trabajo. Asimismo, la interpretación de los resultados y la voluntad de la empresa por mejorar el relacionamiento con sus proveedores y contratistas, conociendo sus necesidades y problemáticas.

Auditoría integral para una administración eficiente

Cr. Nicolás Bertoni

Devic S.R.L., Bahía Blanca, 8000, Argentina

bertonialejandro@gmail.com

Breve reseña de la empresa

Devic S.R.L. es una empresa familiar constituida en el año 1986 que comenzó sus actividades brindando servicios de herrería de obra, en el barrio de Villa Mitre de la ciudad de Bahía Blanca. A lo largo de los años, se fue expandiendo y diversificando las actividades. En 2002 se constituyó como SRL, viéndose con la necesidad de agrandar las instalaciones. Por tal motivo se ha trasladado a un predio propio en el Parque Industrial de Bahia Blanca. Hoy en día, a 34 años de su nacimiento, la empresa cuenta entre sus diversas unidades de negocios, con 110 empleados en la nómina, y presta todo tipo de servicios industriales principalmente en el Polo Industrial de Bahía Blanca, el cual ha sido el principal nicho de mercado durante varios años.
En los últimos años la empresa se ha diversificado y ha emprendido el negocio de fabricación y montaje de aberturas de aluminio, incursionando también más recientemente en la elaboración de hormigón. Con estos dos últimos negocios la empresa ha expandido su clientela a diversos sectores de la ciudad de Bahía Blanca y la zona, ya que anteriormente se concentraba sólo en grandes industrias del Polo.

Problemática detectada

En cuanto a una de las problemáticas que se vio afectada la empresa, se encuentra relacionada al proceso administrativo. El origen del mismo fue el crecimiento de la empresa, la expansión de las unidades de negocio, la cantidad de personal y las nuevas actividades. Todos estos factores han generado que la necesidad de información y el procesamiento de la misma sean cada vez más complejos, potenciado en cuanto a que se trata de un rubro (el administrativo-contable) en cual los directivos que la componen no son idóneos (como lo son, por ejemplo, en el aspecto técnico-productivo).

Esta falencia fue detectada por diversos motivos:

- Se poseía información desactualizada, saldos de clientes, saldos de proveedores, informes de gastos, detalle de facturas pendientes de cobro,

cheques diferidos a pagar, y otros tipos de informes necesarios para gestionar las finanzas de la empresa.

- Había demoras en respuesta a requerimientos de distintas entidades bancarias, en el armado de las carpetas necesarias para calificar, informes solicitados por el estudio contable, y otros requerimientos de los propios directivos.
- Se detectaba cierta duplicidad de tareas en el sector administrativo, como por ejemplo en la emisión de facturas que se realizaban por medio de la página web de AFIP y luego se cargaba al sistema de gestión, se realizaba un cálculo de percepciones y retenciones que luego era validado por el sistema de gestión, se llevaba un Excel a mano con la composición de saldos de clientes que también se cargaba en el sistema, entre otras.
- No se utilizaban todas las herramientas del sistema de gestión administrativo que estaban disponibles, ya que mucha información se manejaba en hojas pasadas a mano o en listados en Excel; como se indicó anteriormente de saldos de clientes, emisión de cheques por medio del sistema, detalle de gastos por concepto, entre otras.
- Había determinados procesos productivos que se querían plasmar en la administración de una forma distinta, con mejoras informáticas que se venían realizando de manera manual; así era el caso de las herramientas o insumos que se retiraban del pañol, o las horas de trabajo que se afectaban a órdenes de trabajo; se realizaba todo a mano y luego se trasladaba a un sistema informático, que ocupaba gran parte del tiempo del personal administrativo.

Solución implementada

Al notarse estas cuestiones y verse imposibilitados de solucionarlo por medios propios, ya sea por parte de los directivos o por los recursos humanos propios de la empresa, se decidió buscar una solución en una consultora externa, planteando que la empresa se encontraba con estos inconvenientes y necesitaban una solución al respecto. Por ello, se recurrió a la Unión Industrial de Bahía Blanca, como entidad gremial empresaria a la que pertenece Devic S.R.L. para buscar una solución al respecto, donde encontró que hay una diversidad de departamentos especializados en estos temas.

Resultados obtenidos

Desde el Departamento de Políticas Tributarias se propuso al respecto realizar una auditoría integral de la administración, mediante un plan de trabajo claro y preciso, con la finalidad de:

- Detectar todas las posibles falencias que se encontraría atravesando la empresa en cuanto al circuito administrativo.
- Informar las consecuencias que tendrían aparejadas las mismas.
- Plantear posibles soluciones para corregir dichas falencias.

La auditoría fue muy satisfactoria en cuanto a:

- Errores detectados en el proceso administrativo, que implicaban diferencias en liquidaciones impositivas, los cuales sirvieron para mejorar de allí en adelante para no repetirlos, con lo cual se ahorraron recursos propios.
- Mejoras en los procesos del sistema de gestión administrativo, ya que se implementaron todas las herramientas del software informático que se poseía pero que se encontraba en desuso por falta de implementación e instrucción al personal administrativo, mejorando así los registros y la disponibilidad de datos.
- Mejoras en los procesos administrativos en cuando a evitar duplicidad de tareas y sintetizar ciertos pasos que eran improductivos, generando una eficiencia en los recursos humanos permitiendo afectar una mayor disponibilidad de los mismos a otras tareas.

La consultoría no solamente culminó con un informe completo de los procesos de auditoría aplicados, las falencias detectadas y las formas de corrección de los mismos, sino que también se instruyó al personal administrativo de cómo llevar a cabo las mejoras propuestas.

Por último, y en base a los buenos resultados que se obtuvieron, se encargó a los consultores la implementación de un nuevo sistema informático para la obtención de la información del sector productivo. Para esto se contactó a una firma desarrolladora que se encargó de plasmarle todas las necesidades que debía satisfacer en cuanto a procesos e información que debía brindar. Por otro lado, se encargó de realizar las pruebas de funcionamiento del sistema, una vez que el mismo fue desarrollado; y también llevo a cabo la capacitación al personal de Devic S.R.L. para la utilización del mismo.

Comentarios finales

Es normal que muchas empresas se encuentren sumidas en el día a día y no dispongan de tiempo para un análisis exhaustivo de sus procesos, tanto técnicos como administrativos. En otras ocasiones, las firmas cuentan con tiempo pero no con recursos económicos.

En este sentido, se destaca la visión y voluntad de los directivos de hacer la auditoría integral, y la respuesta obtenida por parte de la gremial empresaria a la que recurrieron, ya que pudo ofrecerles un servicio profesional y eficiente.

Luego de dichas modificaciones y mejoras, los directivos evaluaron la necesidad de contar con un profesional idóneo en cuestiones administrativas que pudiera mantener eficiente de manera continua los procesos administrativos. Con lo cual, se contrató a un profesional idóneo en la materia dedicado exclusivamente a realizar estos trabajos de organización administrativa interna.

Es muy importante notar que el costo económico de una auditoría integral de estas características, redunda en el corto plazo en ahorros que claramente superan el gasto efectuado. La eficiencia de un sistema administrativo-contable es clave para un manejo integral de los recursos de la firma.

Hoy en día, la empresa se encuentra más que satisfecha en cuanto al procesamiento de la información y de la organización del sector administrativo; quitando de encima la preocupación a los directivos en cuanto al mismo.

Mejora en la competitividad empresarial: acciones implementadas

Marcela Contreras, Luis Contreras y Emily Martínez

Plumas, Bahía Blanca, 8000, Argentina

Breve reseña de la empresa

Plumas es una empresa textil familiar que inició sus actividades en el año 2006 en un garaje de 25 metros cuadrados en la localidad de Bahía Blanca, bajo la dirección de los hermanos Marcela y Luis Contreras. En sus inicios se dedicó a la producción de prendas de noche (sacos, vestidos, remeras, soleras) y ofreciendo sus productos en sus locales. Estas prendas se confeccionaban para marcas del Bahía Blanca Plaza Shopping y para locales del centro comercial de la ciudad. En sus inicios compraban tela por metro y producían un 5% de su capacidad actual. Al dedicarse a confeccionar prendas de moda actual, la empresa no podía contar con grandes volúmenes de stock, ya que la moda cambia permanentemente y muta en cuestión de días.

En términos de superficie y capacidad, en el año 2012 ocupó toda la propiedad donde estaba radicada (100 metros cuadrados), triplicando su capacidad productiva y comprando tela por rollos. En 2018 suma un galpón adicional de 75 metros cuadrados. En la actualidad cuenta con un área total de 200 metros cuadrados más un depósito.

Con el paso del tiempo, la empresa redefinió su orientación en la fabricación de indumentarias y comenzó a dedicarse a la producción de ropa deportiva y ropa escolar, centralizando así sus insumos y utilizando mayoritariamente el color azul.

Posteriormente, Plumas redefinió nuevamente su producción fabril y comenzó a dedicarse a la confección de indumentaria para empresas (pantalones cargo, camperas, camisas, chombas). Asimismo, Plumas brinda a sus clientes una atención personalizada, ya que, si bien cuenta con productos estándar, también confecciona prendas a pedido y especializadas.

Problemática detectada

Al comenzar a vender artículos en grandes volúmenes, la empresa se vio en la necesidad de especializarse y adquirir maquinaria más específica que le permitiera abastecer su elevada demanda, surgiendo así también la necesidad de reducir sus costos de producción.

Por otro lado, a medida que las ventas se incrementaban, comenzaron a formarse dos "cuellos de botella". Uno se debía al poco espacio con que contaba la empresa para colocar los grandes volúmenes que se producían, mientras que el otro se debía a que la mesa de corte utilizada no resultaba lo suficientemente extensa como para lograr los elevados niveles de producción requeridos.

Por otra parte, un inconveniente que era común a todas las empresas textiles de Bahía Blanca era la disminución de la mano de obra capacitada en máquinas industriales, ya que la empresa establecida en la ciudad dedicada a la capacitación de mano de obra a nivel industrial (Torello) decidió cerrar y dar por caducadas sus actividades.

Finalmente, un problema con el que se encuentran todos los proyectos en Bahía Blanca al momento de iniciar sus actividades es la competencia existente con la ciudad de Buenos Aires, ya que, al hallarse las empresas bahienses a una distancia de 700 kilómetros de sus proveedores, se generan elevados costos en los insumos de producción debido al costo involucrado en el traslado de los mismos.

Solución implementada

Con respecto a la necesidad de contar con maquinaria especializada, la empresa adquirió máquinas computarizadas. Estas máquinas cuentan con motor servo y luces led, y consumen energía sólo cuando el operario se encuentra utilizándolas, a diferencia de máquinas industriales más antiguas que consumen energía por el simple hecho de estar encendidas, aunque el operario no se encuentre utilizándolas.

Con respecto al "cuello de botella" generado por el escaso espacio, la empresa logró trasladar el taller a un galpón de mayor superficie, mientras que, en cuanto a la restricción generada por las dimensiones de la mesa de corte, Plumas adquirió una mesa más amplia a la que se le adhirió un carro con ruedas en la parte superior, el cual va desplazándose de un lado a otro con los rollos de tela. Por otro lado, al trasladar el taller a un lugar más espacioso, la mesa de corte también se trasladó allí, ya que anteriormente la mesa se encontraba a dos cuadras de la fábrica.

En cuanto a la necesidad de mano de obra capacitada, junto con gente del Grupo Textil de la UIBB e interactuando con el Consejo Escolar y con la Municipalidad de Bahía Blanca, se formó un curso en el cual personal capacitado en máquinas industriales continúa con la formación de mano de obra profesional, siendo declarado el mismo de interés municipal. El curso se denomina Confeccionando Futuro.

Por último, acerca de la gran competencia que ejerce la ciudad de Buenos Aires, cuando la empresa Plumas se dedicaba a la confección de prendas de noche, realizaba periódicamente viajes a dicha ciudad con el fin de observar las tendencias en moda existentes en los centros comerciales de La Salada, Flores y Once (su competencia en aquel momento), y, de este modo, poder ofrecer al mercado productos diferenciados y con un mayor valor agregado. Luego, al dedicarse a la producción de ropa escolar y

de indumentaria para empresas, Plumas comenzó a comprar grandes volúmenes de escasos insumos, generando así la centralización de los mismos. Finalmente, la atención personalizada que la empresa brinda a sus clientes es la gran diferencia que posee con respecto a sus competidores.

Resultados obtenidos

En primer lugar, las máquinas computarizadas generaron un 30% de reducción de costos energéticos debido al menor gasto eléctrico que conllevan.

En segundo lugar, el traslado del taller a un lugar más amplio y la adquisición de una mesa más extensa, permitió el aumento de la producción y el crecimiento de la empresa, lo que generó un aumento de un 10% en la capacidad de corte, disminuyendo el costo unitario del corte. A su vez, el desplazamiento de la mesa de corte al nuevo taller generó un aumento de la productividad y un ahorro del 10% de los costos por la disminución de los traslados. De igual modo, la adhesión de un carro con ruedas a la mesa de corte permitió una reducción de costos en mano de obra (50% de la encimada), ya que anteriormente, en la mesa se necesitaban dos operarios, mientras que ahora se necesita solamente uno.

Por último, la centralización de los insumos por parte de la empresa también permitió una disminución de los costos debido a los grandes volúmenes de compra y permitió un aumento de su competitividad en el mercado. Esto permitió lograr además crédito con los proveedores, brindándole oxígeno a las finanzas de la empresa, que pudo afrontar grandes licitaciones apalancándose con sus proveedores.

Todos estos ahorros de costos y mejoras en la productividad se traducen en ganancias de competitividad y se resumen en la siguiente tabla:

Problemática	Acciones Implementadas	Resultados
Necesidad de adquisición de máquinas especializadas para abastecer la elevada demanda	Adquisición de máquinas computarizadas	Reducción de un 30% en costo de energía
	Traslado del taller a un espacio más amplio y adquisición de una mesa de corte más extensa	Aumento de un 10% en la capacidad de corte
"Cuellos de botella" generados por el escaso espacio y por tener una mesa de corte pequeña	Traslado de la mesa de corte al nuevo taller	Reducción de un 10% en costos de traslados

	Adhesión de un carro con ruedas a la mesa de corte	Reducción de un 50% en mano de obra para la encimada de las telas
Elevados costos generados por el traslado de los insumos desde la ciudad de Buenos Aires	Realización de grandes compras de insumos, obteniendo créditos con los proveedores que permiten afrontar grandes licitaciones apalancándose con los mismos	Reducción de los costos por el traslado de los insumos, generando un ahorro que se puede direccionar en otras áreas de la empresa

Comentarios finales

La mejora o pérdida de competitividad de las empresas puede analizarse desde las perspectivas micro y macroeconómicas. En muchos casos ambas vertientes funcionan potenciadas y en otras contrapuestas. Se potencian en sentido positivo cuando buenas medidas macroeconómicas generan un incentivo a mejorar puertas adentro, y entre ambas logran mejorar la competitividad. En cambio, en otros casos, ambas tienen una función compensadora de la pérdida de competitividad generada por la otra vía. Este es el caso en que los gobiernos deben tomar medidas sectoriales (por ejemplo, créditos subsidiados, intervenciones de precios, limitaciones al comercio exterior) cuando las empresas no son eficientes. O bien, cuando las firmas deben cambiar estrategias y reinventarse frente a un contexto macro adverso (por ejemplo, por falta de crédito, inestabilidad en el mercado cambiario, inflación alta).

El caso relatado de la empresa Plumas se puede encuadrar en este último ejemplo y no difiere demasiado de la situación que atraviesan numerosas pymes, tanto del rubro textil como de otros. Se rescata de este caso la capacidad de reaccionar a tiempo y cambiar de estrategia, a la vez que apoyarse en un grupo de pares para la búsqueda de soluciones conjuntas.

Confeccionando Futuro: curso técnico con función social

Gustavo Lari, Luis Contreras, Nerina Muñoz

Sueño Austral, Plumas, UNS; Bahía Blanca, 8000, Argentina

gustavolari@suenoaustral.com.ar, fabricaplumas@live.com

Breve reseña

Creado desde el departamento de los Jóvenes Empresarios de la Unión Industrial en el año 2012, GRUPO TEXTIL es un espacio que reúne a las empresas, ya sean fábricas o talleres del área textil de Bahía Blanca y la zona de influencia, con el objetivo de establecer políticas estratégicas para lograr el crecimiento competitivo como así también aumentar las ventas y reducir diferentes costos en materia prima, mano de obra calificada, logística de distribución y comercialización, entre otros objetivos.

Asimismo, cumple una función social brindando cursos y capacitaciones, con el objetivo de que los alumnos aprendan y adquieran diversos conocimientos para que en un futuro puedan contar con un emprendimiento personal.

El objetivo del grupo es nuclear, representar y promover el área textil con el fin de incentivar el desarrollo de fábricas y talleres en nuestra ciudad y la región, generando valor agregado y puestos de trabajo, fomentando la innovación, competitividad, inversión y desarrollo sustentable de la economía local y regional, con un compromiso en el cuidado del medio ambiente y la responsabilidad social empresaria. El mismo tiene como espacio físico la casa matriz de la Unión Industrial de Bahía Blanca.

Algunas de las empresas que forman parte del mismo son: Plumas. Fábrica de indumentaria, Sueño Austral, Bordatech Bordados, Papelera Morus, Serigrafía Gómez, El Vaticano.

Problemática detectada

La problemática surgió del diálogo entre un conjunto de industriales de distintos rubros que tienen en común la constante necesidad de mano de obra calificada y/o especializada. En otras palabras, un grupo de empresarios de la ciudad manifestaron la persistente escasez de oferta de mano de obra capacitada para cubrir puestos en la industria textil.

Muchos operarios y/o emprendedores solo contaban con conocimientos de manejo de máquinas familiares que en muchas ocasiones quedaban obsoletas para ciertos

trabajos, por lo tanto, era necesario otorgarles la posibilidad de capacitarse con máquinas industriales para que puedan progresar.
Individuos que buscan emplearse y no están capacitados = exceso de oferta que se busca capacitar
Empresas que requieren de mano de obra calificada = demanda insatisfecha que se busca cubrir

Solución implementada

Entre las distintas empresas que componen Grupo Textil, la UIBB y el Consejo Escolar se creó el curso "CONFECCIONANDO FUTURO" como respuesta a la necesidad de mano de obra calificada, la falta de emprededorismo y la ausencia de capacitación en los operarios del rubro textil. El mismo se concretó conjuntamente con el Centro de Formación Profesional Nro. 404 de General Cerri.

Se trata de una capacitación gratuita en la que los alumnos adquieren conocimientos en confección industrial de textiles realizando sus prácticas en el taller textil que cuenta con máquinas industriales. Con esto se busca que adquieran la capacidad de diseñar con autonomía sus confecciones para que en un siguiente paso puedan comercializarlas y desarrollar su propio emprendimiento textil. Además, se realizan visitas a fábricas textiles para que los alumnos vivencien y experimenten el espíritu empresarial.

Por otro lado, se les brinda talleres de diseño, emprededorismo, y charlas de coaching de manera que conozcan las experiencias de otros. Asimismo, cuentan con un taller de administración de empresas que tiene como objetivo que el alumno que egresa sea capaz de realizar un presupuesto de su negocio, calcular sus costos, como así también tener una idea general de cómo funciona un monotributo y cuáles son los beneficios que este trae.

Las clases teóricas y prácticas son dictadas en las instalaciones de la UIBB. El dictado del curso dura un cuatrimestre, brindando dos cursos al año con un cupo máximo de 25 alumnos por curso. Las únicas condiciones para ingresar es ser mayor de 16 años y haber culminado la educación primaria.

Por otro lado y con el fin de incentivar a los emprendedores se implementaron línea de créditos con distintos bancos y la Municipalidad de Bahía Blanca. Se trata de créditos que no generan intereses en donde el cumplimiento del pago total del mismo habilita a adquirir un crédito mayor el siguiente año.

"CONFECCIONANDO FUTURO" funciona como un "mercado de trabajo" en donde los alumnos una vez capacitados y egresados del curso tienen la posibilidad de ingresar a las distintas fábricas y/o empresas que requieran de tal mano de obra.

Resultados obtenidos

El desarrollo del programa generó grandes oportunidades de desarrollo de emprendimientos a nivel local y formó mano de obra calificada para las empresas textiles con los egresados. Es decir, se creó un mercado de trabajo en donde personas que se encontraban desempleadas fueron capacitadas y lograron cubrir la demanda de mano de obra calificada insatisfecha de las distintas fábricas.

Esto no sólo otorga un ingreso al alumno y un beneficio a la empresa, sino que también cuando una persona es capacitada y logra crear algo por sí misma se siente empoderada. En este sentido, el individuo se siente capaz de independizarse y más útil. A su vez, cuenta con mayores habilidades para desarrollarse día a día y con esperanzas de progreso

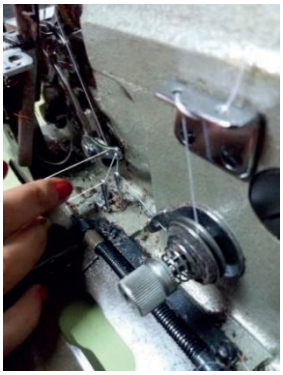
De forma complementaria creó relaciones entre los integrantes del curso brindando la capacidad de apalancarse mutuamente con sus emprendimientos de forma conjunta, generando cooperativismo entre sí.

Tabla 1. Indicadores de los cursos CONFECCIONANDO FUTURO

Egresados en 6 años (dos cuatrimestres por año)	275
Alumnos que se asociaron formando grupo	6
Alumnos que obtuvieron crédito del municipio	1
Alumnos que adquirieron máquinas (con ayuda del Grupo Textil)	6
Alumnos que ingresaron a trabajar por el curso	5
Alumnos que realzaron prácticas	10
Alumnos que trabajan desde sus hogares	25
Alumnos que realizaron tutoriales Paso a Paso por TV	5

Cabe destacar que los casos contabilizados en esta tabla son aquellos de los que se tiene conocimiento, es decir, en varios ítems debe haber más alumnos, pero se desconoce el número ya que no se realiza un seguimiento personalizado.

Comentarios finales



“CONFECCIONANDO FUTURO” lleva 6 años de continuidad y fue declarado curso de interés municipal. Además, tuvo participación en la bolsa de trabajo de la Municipalidad de Bahía Blanca, brindándoles capacitaciones a algunos de los inscriptos en la misma que se encontraban desempleados en ese momento.

Por otro lado y debido a la gran repercusión del curso en el área textil, cuatrimestralmente sólo logran llevar adelante el curso el 25% de los inscriptos, ya que por la capacidad de las instalaciones se debe poner un máximo de alumnos por cuatrimestre. Todo esto da cuenta de la gran potencialidad que tiene esta actividad.

Se refleja en esto la importancia de generar espacios para que personas que por distintas razones no pueden acceder a una educación secundaria, terciaria y/o universitaria tengan la posibilidad de contar con herramientas para desarrollarse y llevar a cabo su propio negocio sin una dependencia directa.

Documentos fotográficos

Modificación en el sistema de retornabilidad de envases de Coca-Cola

Rodrigo Introcaso

Coca Cola Andina, Bahía Blanca, 8000, Argentina

rodrigointrocaso@gmail.com

Resumen

Los empaques retornables de vidrio y el llamado Ref-Pet (Refillable Pet) son claves dentro del portafolio de la compañía ya que ofrecen al consumidor una opción de consumo a un precio asequible, especialmente bajo condiciones económicas difíciles.

Sin embargo, la llamada "retornabilidad" presenta grandes desafíos, no sólo vinculados al consumidor y su proceso de compra, sino también dentro del llamado "Sistema Coca-Cola" que incluye un alineamiento entre la compañía, los embotelladores, la fuerza de ventas y el canal.

Entre algunos desafíos se destacan la complejidad operativa de producción de envases, la falta de incentivos para los integrantes del sistema, el retornable como experiencia de compra inferior y de baja calidad donde el comprador suele sentirse un "comprador de segunda", la baja practicidad del proceso de compra, envases desgastados y con apariencia de falta de higiene, entre otros.

Bajo este contexto nace un plan de reconversión del negocio, en el que se define un nuevo marco estratégico para la retornabilidad, alineando los elementos intervinientes en el sistema para ofrecer no sólo un producto asequible sino también una mejor experiencia de compra.

El trabajo pretende mostrar cómo impactó (e impacta) - particularmente en el área operativa de embotellado de la bebida - una de las acciones más significativas en esta nueva estrategia: la migración del envase serigrafiado (ACL) a envase genérico o multi-producto.

Palabras clave: Estrategia, envase retornable, multi-producto.

1 Situación histórica VS ideal

Los desafíos planteados en el resumen, sumados a una caída del consumo, hacen que la estrategia de Coca-Cola esté enfocada en reforzar los programas de retornables y la diversificación de las presentaciones es un punto clave.

Rediseñar el empaque retornable implica generar un cambio para resignificar su imagen y evitar ser percibido como de segunda categoría. Es importante generar esta conciencia desde las etiquetas y la calidad del envase y transmitirlo así a todo el sistema.

Se busca asegurar un nuevo diseño que permita por un lado el reposicionamiento del empaque para que luzca de calidad, tanto en vidrio como en plástico, y por otro,

que facilite la mecánica operativa en las plantas embotelladoras. Para esto último, la introducción de etiquetas de papel permite la flexibilidad operativa de producción frente a la demanda estacional de diferentes sabores. De esta manera se genera un empaque multi-producto que además da pie a la libre intercambiabilidad de envases.

Tabla 1. Principales impactos en las operaciones de las distintas áreas

	ACL (Applied Ceramic Label)	**Multi-producto**
Marekting	Imposibilidad de adaptar la imagen a situaciones concretas (ej: Navidad)	El arte de la etiqueta puede adaptarse fácilmente, según se requiera
	Las promociones quedan limitadas al color de la tapa (sin información alguna)	La etiqueta de papel puede contener la información y la imagen
Venta	El ACL sufre un desgaste que no es bien percibido en la góndola	El envase tiene una mejor imagen a pesar del desgaste del PET
	El comerciante devuelve los envases sin clasificar dentro de cajones	No es necesario que el comerciante clasifique los envases dentro de los cajones
Transporte	Los camiones sólo cargarán los envases del sabor que corresponda en cada caso	La carga de camiones es más eficiente
	Posible capacidad ociosa	No hay capacidad ociosa
Almacenamiento	Es necesario un proceso de clasificación de envases por sabor (líneas de sorting o personal exclusivamente dedicado a hacer la tarea manualmente)	Los envases se introducen en la línea tal como llegan desde el comercio
	Los envases vacíos deben almacenarse en estibas individuales (por sabor)	Las estibas de envases vacíos son únicas
	Mayor espacio utilizado en el depósito	Mejor aprovechamiento del espacio en el depósito
Embotellado	La clasificación manual de envases no es suficiente	No es necesaria la clasificación manual
	Cada equipo inspector de la línea de producción debe estar calibrado para cada sabor	Las variables de ajuste de los equipos se reducen significativamente
	Frecuentes incumplimientos de la planificación por falta de envases disponibles en planta	Envases siempre disponibles por mejor ciclo de retornabilidad
	Mayores tiempos entre cambios de sabores	Menores tiempos entre cambios de sabores

2 Situación actual

Una decisión estratégica de este tipo implica grandes desembolsos de dinero. El análisis sobre dónde, cuándo y cómo llevar a cabo la migración debió ser lo más detallado posible.

La planta de Bahía Blanca fue la elegida por Coca-Cola Andina para iniciar este cambio en 2017, y la manera de migrar el parque de botellas fue gradual. Actualmente, la proporción de envases llenados en ACL es del 20%. Pero en poco tiempo, los sabores de Fanta y Sprite (y más tarde Coca-Cola) serán envasados 100% en envase genérico debido a que la no renovación del parque serigrafiado hace que la calidad de las botellas que están en el mercado haya llegado a su límite inferior.

Si bien todo parece indicar que la introducción del nuevo envase es la solución a un gran número de limitaciones, en la práctica se observaron muchos desafíos, surgidos de la coexistencia del ACL y el multi-producto, a saber:

- La clasificación de envases se complejizó al incorporarse un nuevo grupo de botellas que, si bien es indistinto la etiqueta que tengan, deben separarse del envase con ACL por cuestiones operativas y logísticas.
- Se añadieron muchas más variables a los equipos inspectores (por imágenes), algunos de los cuales no fueron diseñados para tal fin, por lo que debieron parametrizarse adecuadamente o bien debió incrementarse la labor manual (ej: una etiqueta mal pegada puede ser interpretada como un objeto extraño, produciendo un falso rechazo)
- La frecuencia de lavado de filtros de la lavadora de botellas y la mantención general del sistema de extracción de etiquetas se incrementó casi un 100%, pasando de ser una tarea de mantenimiento planificado a un trabajo diario del operador de producción.
    - La máquina debió ser intervenida por el fabricante para aumentar el nivel de extracción de etiquetas.
- La etiquetadora pasó de ser un equipo prácticamente en desuso – únicamente se usaba en el formato de 2,5 L – a cumplir un rol fundamental en el proceso de embotellado.
    - La optimización en el uso del adhesivo de etiquetas fue motivo de un proyecto de mejora llevado adelante por supervisores y operadores.
    - Debió elaborarse un plan de capacitación de personal para garantizar la presencia de un titular en cada puesto de trabajo.
- Debió implementarse un sistema diferenciado de rotulación de pallets para garantizar que los dos tipos de envases lleguen por separado a los destinos en que no existe clasificación a la hora del retorno a planta.
- El reciclado del envase “clear” fue un punto muy positivo, pero también agudizó la inspección del envase rechazado en la línea y añadió varias tareas más al proceso de descarte –segregación, identificación y disposición final diferenciada -.

3 Conclusiones generales y particulares

Los envases retornables son clave dentro de un portafolio balanceado. Por un lado, ofrecen una opción de consumo asequible bajo condiciones económicas difíciles y por otro, asegurando una compra inteligente y ecológica. Funciona tanto como una herramienta de penetración y acceso para los segmentos económicos más bajos como así también para los más altos.

Dentro del portafolio, cumple la función clave de asegurar el ingreso, afianzar la frecuencia de consumo y permitir el escalamiento hacia productos de mayor tamaño.

Sin embargo, el camino del crecimiento de la retornabilidad en Argentina presenta muchos desafíos.

Es fundamental lograr una estrategia integral unificada y alineada a todo el sistema para generar un valor agregado diferencial para afianzar el camino de crecimiento en un contexto de negocios cada vez más dinámico y competitivo.

Los puntos mencionados en el apartado 2 (y varios otros) hablan de la complejidad que conlleva una decisión de este tipo cuando pretende realizarse a gran escala. Cuantas más áreas se vean involucradas en la decisión, mayor será la complejidad.

Es fundamental lograr una clara comunicación - entre las áreas y entre los distintos escalafones de una misma área - de todas las acciones surgidas del plan maestro, para minimizar la pérdida de tiempo en un proceso extenso por naturaleza.

Estudio del aumento de la capacidad de molienda en sistemas de producción de alimentos balanceados

Jacquelina Claudia Lobos de Ponga[1, 2], Agustina Di Battista[1, 2], Sofia Bonifacino[1], Melisa Sequeira[1], Ivana Cotabarren[1, 2], Juliana Piña[1, 2]

[2] Planta Piloto de Ingeniería Química – PLAPIQUI (UNS-CONICET), Bahía Blanca, Argentina
jlobos@plapiqui.edu.ar

Resumen

La molienda es una etapa fundamental en el proceso de elaboración de alimentos balanceados debido a que determina la distribución de tamaño de partícula de los ingredientes, y ésta última influye en la digestibilidad y palatabilidad del producto. El maíz, cuya reducción de tamaño se realiza en una primera etapa de molienda, constituye el principal ingrediente en las formulaciones de nutrición animal, por lo que la capacidad de molienda del mismo es proporcional a la capacidad de producción. Con el fin de aumentar la capacidad de molienda industrial en un proceso de producción de alimento balanceado, se estudia la incorporación de un by-pass de la corriente de maíz molido mediante la incorporación de una zaranda que únicamente dirige el maíz pasante a la etapa de extrusión, evitando una molienda innecesaria. Para ello, se determinó el tamaño de apertura de zaranda que permite mantener la distribución de tamaño especificada al ingreso de la etapa de extrusión. En primera instancia se requirió la adecuación de la etapa de molienda piloto (escala de realización de ensayos) a la escala industrial. Establecidas las condiciones operativas en el molino piloto, se estudiaron 4 tamaños posibles de apertura de zaranda. El tamaño elegido es el que reprodujo la distribución y tamaño medio de partícula del proceso original, logrando aumentar la capacidad en un 16,36 %.

Palabras clave: Molienda, maíz, alimento balanceado, zaranda.

1 Introducción

El proceso de reducción de tamaño de partícula aumenta la superficie por unidad de volumen de los ingredientes, provocando que una mayor porción del interior del grano esté expuesto a enzimas digestivas, permitiendo un mayor acceso a componentes nutricionales como el almidón y las proteínas. [1]
El estudio del aumento en la capacidad de molienda en sistemas de producción de alimentos balanceados, es de gran importancia debido a que los principales ingredientes de las formulaciones requieren en ocasiones, más de una etapa de molienda para alcanzar la calidad requerida.

2 Materiales y métodos

Descripción del proceso industrial

La producción de alimentos balanceados incluye etapas de molienda de la materia prima (granos de maíz, afrechillo, soja, etc.), que son determinantes para las etapas de producción posteriores (mezclado, extrusión). En la Fig. 1.a, se presenta el diagrama del proceso industrial bajo estudio, que consta de una primera etapa de molienda de maíz, cuya harina (A) se envía a un mezclador con el resto de los ingredientes de la formulación (F) para alimentar a una segunda etapa de molienda (C) que genera la distribución de tamaño adecuada (B) para las posteriores etapas del proceso. Con el objetivo de lograr un aumento en la capacidad productiva, se propone la incorporación de una corriente de by-pass (BP) mediante la incorporación de una zaranda, que permita dirigir el maíz que ya posee el tamaño medio y la distribución de partícula (DTP) requerida directamente a la corriente de alimentación de la etapa de extrusión (B') (Fig.1.b).

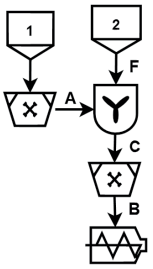

Fig.1.a. Diagrama simplificado del proceso industrial de alimentos balanceados.

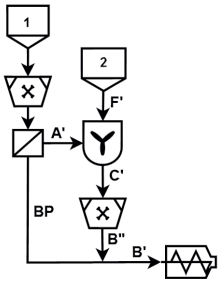

Fig.1.b. Diagrama simplificado del proceso industrial con corriente de by-pass.

Si el caudal de alimentación al segundo molino se mantiene invariante, las corrientes B y B''resultarán iguales. El aumento de caudal será atribuido a la corriente BP. Podrá estimarse mediante la relación BP/B, con la fracción de maíz retenido y de maíz global de la formulación.

Caracterización de muestras

La DTP se caracterizó mediante la utilización de un equipo vibrador de laboratorio (Zonytest, Argentina). Se utilizaron los tamices ASTM: 8 (2,240 mm), 12 (1,600 mm), 16 (1,120 mm), 20 (0,800 mm), 30 (0,560 mm), 40 (0,400 mm), 50 (0,300 mm), 70 (0,212 mm), 100 (0,150 mm), 140 (0,106 mm) y 200 (0,075 mm). Se tamizaron muestras de 100 gramos sometidas a 5 minutos de vibración. Se registró la masa retenida en cada tamiz. El procedimiento se realizó dos veces por mezcla, reportándose los valores promedio.

Determinación de las condiciones operativas en el molino piloto

El equipo de molienda piloto utilizado para la reproducción de las condiciones de molienda del segundo molino industrial fue un molino de martillos Fitzpatrick modelo DAS06 (Waterloo, Canadá) con velocidad de cuchillas variable y cribas intercambiables. Con el fin de proporcionar una alimentación continua y constante al molino, se utilizó un alimentador de tornillo de frecuencia variable. Además, se determinó el tiempo de estabilización para cada caudal mediante el registro de la potencia consumida. Se ensayaron tres caudales de alimentación al molino piloto, operado a 4600 rpm y con una criba de 1 mm de apertura de malla. En cada ensayo, se tomaron muestras del material molido cada 10 segundos, en intervalos de 20 segundos y se registró el consumo de potencia. El caudal elegido, fue el que permitió reproducir la DTP y el tamaño medio geométrico de la corriente B industrial en condiciones estacionarias.

Preparación y determinación de mezclas para molino piloto

La composición de maíz en la corriente B industrial fue de 55, 14 %. Por lo tanto, las corrientes A' y BP deben constituir la misma fracción de maíz en la corriente B'. El caudal de cada una de ellas, es función el tamaño de malla a utilizar en la zaranda. Bajo la misma consideración, se prepararon las mezclas de alimentación al molino piloto.

3 Resultados y discusión

Caracterización de muestras industriales

La corriente de maíz que ingresa al segundo molino (A) posee una proporción de la DTP de la corriente industrial B. Sus diámetros medios geométricos son de 609,0± 2,1 μm y 320,8 ± 2,1 μm respectivamente. Se propone estudiar el efecto del by-pass generado por aperturas de zaranda correspondientes a mallas ASTM 20, 40, 50 ó 70.

Determinación de las condiciones operativas en el molino piloto

Los caudales ensayados en el molino piloto correspondieron a 10 Hz (B1), 30 Hz (B2) y 40 Hz (B3) de operación en el alimentador. La corriente B1 fue la que mejor reprodujo la DTP de B. Su diámetro geométrico resultó de 334,8± 2,1 μm. Por lo tanto, las condiciones operativas del molino piloto quedaron definidas por una frecuencia de alimentación de 10 Hz, una velocidad de cuchillas de 4600 rpm y una criba de 1 mm.

Determinación del tamaño de apertura de zaranda de la corriente by-pass en escala piloto

Se tamizaron muestras de la corriente A, utilizando las mallas ASTM 20, 40, 50 ó 70. Los porcentajes de maíz pasante-retenido que definieron a las corrientes BP y A'

fueron 63,99-36,01%, 37,88-62,12%, 25,16-74.84%, y 11,88-88,12% respectivamente.
Las muestras A' resultantes se mezclaron con muestras de F' respetando la formulación. Posteriormente, se alimentaron al molino piloto. La DTP y el tamaño medio de cada corriente B' obtenidas a escala piloto, se presentan en las Fig.2.a y Fig.2.b, junto a la corriente B1.

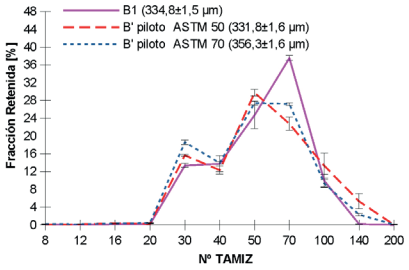

Fig. 2.a. DTP y diámetro medio geométrico de las corrientes B' piloto con tamaños de mallas ASTM 50 y 70 y de la corriente B1.

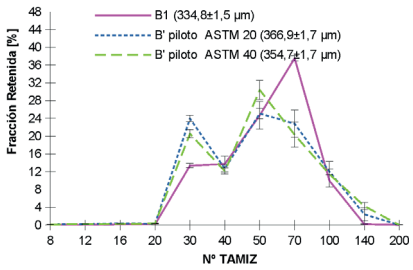

Fig. 2.b. DTP y diámetro medio geométrico de las corrientes B' piloto con tamaños de malla ASTM 20 y 40 y de la corriente B1.

Las mallas que mejor representan la DTP y el tamaño geométrico medio de B1, son las ASTM 40 y 50.

4 Conclusiones

La utilización de una malla ASTM 40 para la implementación de un by-pass en la corriente de maíz molido incrementaría el caudal de producción en 21,31 %, mientras que la utilización de una malla ASTM 50 en 16,36%. Debido a que segunda reproduce la DTP y el tamaño medio geométrico de la corriente B industrial con mayor similitud, se concluye que la mejor opción para la implementación de la zaranda es la malla ASTM 50.

Programa motivacional en una PyME bahiense

Ariel Muzi

METROpallets, Bahía Blanca, 8000, Argentina

info@metropallets.com.ar

Breve reseña de la empresa

METROpallets es una recicladora de pallets para la industria. Obtiene los mismos a través de su red de más de mil proveedores distribuidos por el país abasteciendo a la industria alimenticia, agroindustrial y minera con alcance nacional.

Nació como un emprendimiento unipersonal y fue multiplicando su producción desde su creación, en el 2011, llegando hoy día a 12 empleados directos y 10 tercerizados. Con una recuperación anual de más de 300.000 pallets que permite abastecer a más de 100 industrias de la región. Su creación respondía a la necesidad en el mercado de una oferta formal de pallets usados que honre el concepto de la economía circular.

El desarrollo de la actividad permitió conocer a su titular la problemática existente en sector social más vulnerable de la Argentina y la necesidad imperiosa de encontrar soluciones al flagelo del mercado laboral informal. Fue así que la empresa transitó los caminos de la Certificación Internacional como Empresa B desarrollando distintos programas para mitigar la huella de carbono y la desigualdad social, como el programa Despertando Talentos, METROretos, Soy Arbol, Guardianes del Planeta y Hola Abuelos.

Su condición de ser la única Empresa B certificada de la ciudad de Bahía Blanca, le confiere una característica más que especial, donde el triple impacto está en cada decisión de negocio.

Problemática detectada

Por tratarse de una empresa pequeña, de 12 empleados, y donde la pirámide de jerarquías es muy reducida, se detectó un comportamiento que a su vez es propio de la mayoría de las dotaciones de personal de las empresas pequeñas: falta de compromiso a raíz de una ausencia de horizonte de crecimiento dentro de la organización. Esta característica, se origina principalmente por la falta de estímulo y por ende, pérdida de confianza en sí mismos. Se puede concluir que la falta de compromiso atenta, además

de la pérdida de calidad de vida, a la pérdida de productividad dentro de la organización.

Solución implementada

La firma desarrolló un programa denominado Despertando Talentos. El mismo está basado en un Role Play, donde cada colaborador, "juega" a liderar un área distinta de la empresa cada treinta días, conduciendo a todo el equipo de trabajo en lo que a esa área respecta.

Cada colaborador lidera un área. Hoy, son 11 las áreas asignadas:

1. General
2. Herramientas
3. Sustentabilidad
4. Administración Financiera Hogareña
5. Auto elevadores
6. Producción
7. METRO-retos
8. Infraestructura
9. Tecnología
10. Personal o RRHH.
11. Guardianes del Planeta.

Como herramientas, se utilizan reportes gráficos manuales basados en el proceso KAISEN y reportes de frecuencia diaria online, mediante Formularios de GOOGLE. También se apalanca en distintos grupos de interés formados por WhatsApp más el soporte de la app UAALOO. La información generada es procesada y analizada para realizar el feedback correspondiente.

Resultados obtenidos

Se pueden clasificar los beneficios obtenidos en dos grandes áreas: la inherente a la empresa y la inherente a los empleados.

Se podrá ver como algunos beneficios son comunes para ambas áreas, lo que le confiere al programa, características más que interesantes para su implementación.

Para el colaborador, se pueden mencionar, entre los más relevantes, los siguientes beneficios:

- Desarrollo de la capacidad de liderar "sin cargo".
- Desarrollo del poder de "negociación". Sin él no lograría los objetivos que se le plantean.
- Desarrollo del poder de la comunicación efectiva.

- Desarrollo del poder de planificación y organización para evitar los conflictos.
- Desarrollo de la capacidad de "súper" visión.
- Fortalecimiento sobre los conocimientos en sustentabilidad, tecnología y administración financiera hogareña, los cuales son de alcance personal.
- Reconocimiento de las ventajas de liderar en un marco con reglas claras, basadas en el proceso KAISEN.
- Desarrollo en conocimientos técnicos inherentes de la empresa, incluyendo manejo de maquinarias.
- Desarrollo de la confianza en sí mismo. Generando decisiones más asertivas.

Para la organización, se pueden mencionar los siguientes beneficios:

- Atomización y distribución equitativa de responsabilidades.
- Dilución del concepto "irremplazable" de ciertos colaboradores al generar valor y conocimientos en el resto de colaboradores.
- Optimización de los procesos al profesionalizar a cada colaborador.
- Eliminación de conflictos entre colaboradores y empresa por la mejora en la calidad de comunicación y el empoderamiento de cada uno.
- Eliminación del "anonimato" a la hora de encontrar responsables de episodios desafortunados inherentes a la actividad de la organización.
- Reducción drástica del nivel de conflictividad con sindicato a raíz de la mejor calidad de relación con colaboradores.
- Mejora en la productividad del 12%. (últimos 12 meses).
- Reducción de la inasistencia por accidentes laborales en un 90%.

Comentarios finales

El uso del formato del Role Play invita a enfrentar los desafíos sin el clásico temor al fracaso, entonces el escenario se convierte en propicio para que cada colaborador saque lo mejor de sí, incluso sin que ellos mismos sepan que contaban con determinadas aptitudes.

Cada colaborador vive la experiencia con expectativas, ganando día tras día, un logro nuevo. Este ejercicio le permite visualizar con mayor claridad las herramientas que tiene disponible como también las reglas de juego en las cuales debe moverse.

Asimismo el colaborador nota muy rápidamente que se horizontaliza la estructura de la organización, permitiendo que su opinión sea contemplada por todos, a diferencia del pasado, donde su opinión sólo era escuchada por su jefe directo.

Para el empleador, la experiencia también es gratificante. Si bien lleva un gran trabajo en la implementación y control, los resultados en el comportamiento de cada integrante del equipo, permite llevar la empresa a otro nivel de profesionalismo,

descansando responsabilidades de manera más atomizada entre todos, y por ende, mejorar la productividad y la convivencia.

Como conclusión, el proceso implementado arroja beneficios indiscutibles para todas las partes involucradas.

Sistema logístico integrado para la gestión operativa de carga y despacho de camiones

Augusto Ferraro, Joaquín Alencastre Cordi

PBB Polsiur SRL, Bahía Blanca, CP 8000, Argentina

aferraro@dow.com jalencastrecordi1@dow.com

Resumen. Este trabajo presenta una visión general de un sistema para poder tomar decisiones de forma eficiente en la gestión diaria del despacho de camiones de polietileno palletizado en el site logístico de PBB Polisur, Bahía Blanca. Su objetivo es utilizar los recursos logísticos y operativos de la manera más competitiva posible, garantizando la entrega de órdenes de clientes en tiempo y en forma. Para ello, se cuenta con recursos limitados: por un lado, existen distintos proveedores logísticos con una disponibilidad variable de camiones para la carga de órdenes. Por otro, los recursos operativos para el despacho de camiones son limitados y es menester usarlos de manera eficiente. Los clientes se encuentran distribuidos en distintos puntos del país y existen fechas de entrega planeadas que deben respetarse a fin de cumplir con las expectativas de los clientes. Los distintos proveedores tienen tarifas distintas para cada destino y conjuntamente existen compromisos en los porcentajes a cumplir para cada ruta y para cada transporte. Para la resolución de este problema complejo, se diseña un sistema que contemple estas restricciones y variables para poder conseguir una solución eficiente.

Palabras clave: logística, Supply Chain, gestión por procesos, secuenciamiento de operaciones, Sistemas ERP, gestión de operaciones, asignación de proveedores.

1 Definición del problema

1.1 Descripción de la operación de despachos

Para poder cumplir con el despacho de camiones, existe un proceso definido en el que actúan varios actores. El proceso comienza con la presentación de un camión en el sector de precarga. Aquí, se realiza un chequeo de las condiciones de la unidad y de la documentación con la que debe contar el chofer para poder seguir con la carga. Si existe algún desvío en este punto, el transporte deberá corregirlo. De lo contrario, la unidad será rechazada.

Luego de haber realizado un chequeo de las condiciones con las que debe cumplir la unidad y el chofer, el sector operativo se comunicará con el sector de precarga para enviar la unidad a cargar.

El sector operativo tiene la carga preparada para comenzar con la carga del camión. Aquí intervienen recursos operativos (auto elevadores, grúas pórtico, reach stackers, inspectores de calidad).

Una vez que el camión finaliza su carga, procede a enlonar si corresponde y es pesado nuevamente. Se le entregan los documentos necesarios (remito, certificaciones de calidad del producto) y finalmente, comienza su tránsito al cliente.

1.2 Definición de condiciones del problema

La descripción anterior permite comprender los pasos que debe seguir cada unidad a despachar para poder comenzar su tránsito al destino asignado. Esta situación requiere del recurso logístico (camión y chofer) y de recursos operativos (personal del sector de precarga y recursos necesarios para la operación del despacho). En ambos casos, ambos recursos son limitados: los camiones con sus choferes pueden no estar disponibles a primera hora para su despacho. Al contrario, su disponibilidad dependerá de la gestión de los recursos del transporte y de la demanda que se le solicite. Además, existen distintos tipos de camión necesarios para cada orden de venta dependiendo del *payload* de la carga.

Por otro lado, los recursos operativos también son finitos. No es posible cargar simultáneamente una cantidad ilimitada de camiones, sino que existe una capacidad limitada para poder llevar adelante esta operación.

1.3 Objetivos e indicadores de la gestión del proceso de despachos

Los principales indicadores a considerar en la gestión de los despachos serán:

1. Concretar el despacho de los camiones en tiempo: para poder llegar a los clientes en la fecha esperada, es necesario cumplir con los tiempos planeados en el despacho.
2. Cumplir con las cuotas pactadas por el sector de compras: cada transporte participó en un proceso de licitación donde se asignaron porcentajes para cada ruta que deben cumplirse lo más fielmente posible. Eso conducirá a tener una estructura de costos logística competitiva.

1.4 Variables de decisión

Dadas estas restricciones que fueron mencionadas en la anterior sección y los objetivos que deben perseguirse de manera continua, tenemos que considerar cuáles son las variables sobre las cuáles es posible actuar y que permiten conseguir mejores resultados en la gestión del proceso.

En primer lugar, la decisión más importante es el proceso de asignación, en donde cada orden de cliente se asigna a un transporte en particular. Esta decisión será fundamental a la hora de conseguir los resultados esperados. En segundo lugar, la determinación de un horario de carga para cada camión será sustancial para poder gestionar los recursos operativos de manera eficiente.

Contemplando tanto las variables como las restricciones, se busca diseñar un proceso que cumpla con los objetivos del dador de carga.

2 Descripción del proceso de gestión

2.1 Actores que intervienen en el proceso

Para comprender el proceso de gestión de los despachos, es importante definir cuáles son las partes que intervienen durante todo el proceso:

1. Mode of Transport Scheduler (MOT Scheduler): se trata de la persona que coordina y es responsable de la totalidad del proceso y pertenece al dador de carga.
2. Carrier: se define así al transporte que será responsable de comunicarse con el MOT Scheduler para disponibilizar las unidades necesarias para el despacho de camiones y de presentarlas en el tiempo convenido para cumplir con los programas operativos.
3. Site Logistics: se trata de la parte responsable de usar los recursos operativos para concretar el despacho de los camiones presentados en el sector de precarga.

2.2 Diagrama del proceso

El siguiente diagrama indica los pasos más importantes del proceso con los responsables correspondientes. En la primera fila, se indica una línea de tiempo referida al día *D*, que indica el día planeado para el despacho.

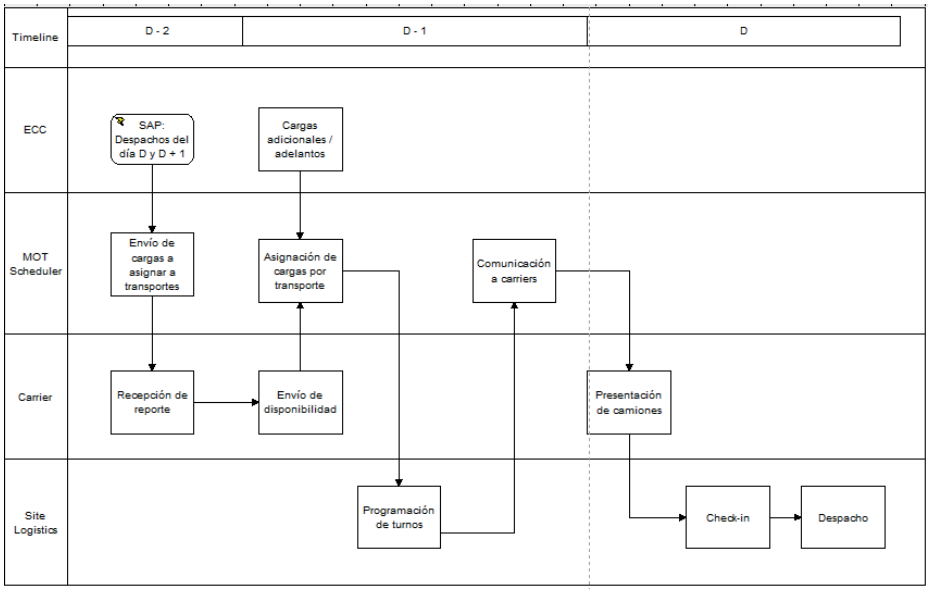

Fig. 1. Diagrama del proceso

El proceso comienza con la información de cargas que deben ser despachadas el día D y D + 1. Esta información indica para cada orden de venta, el destino al que se debe entregar y tipo de camión que se debe utilizar. Esta información es procesada por el MOT Scheduler y proyecta las necesidades a los transportes indicando un horario estimado de carga en un rango definido que depende del tiempo de tránsito que se tenga al cliente y la fecha de entrega planeada.

Cada carrier (transporte), será responsable de recibir esta proyección de cargas con la necesidad estimada en la que deben presentarse las unidades. El día siguiente (*D – 1),* responderá al MOT Scheduler con la disponibilidad que contará el día *D*, indicando en qué rango horario podrán presentarse en pregate, a qué destino pueden asignarse y de qué tipo de camión se trata.

Contando con la información de disponibilidad logística de cada carrier, y agregando órdenes de venta que puedan ser imprevistas, el día *D – 1*, el MOT Scheduler realizará la asignación de órdenes de venta a cada transporte mediante una regla heurística que respete los porcentajes asignados de cada ruta en la licitación previa y que cumpla con el rango horario estimado para poder llegar al cliente a tiempo.

Con esta información, el sector operativo determinará un horario específico en el que se deberá programar el despacho de cada camión, considerando la capacidad operativa instalada y los recursos disponibles. Esta información será recibida por el MOT Scheduler que la retransmitirá a los transportes.

Cada uno de ellos, será responsable de presentar las unidades en el horario pactado para poder cumplir con la programación realizada por Site Logistics. El proceso finaliza con el despacho del camión y su tránsito al cliente.

Innovación en la industria petroquímica

Cristian Zurlo, Mateo Pilia y Xoana Alimenti

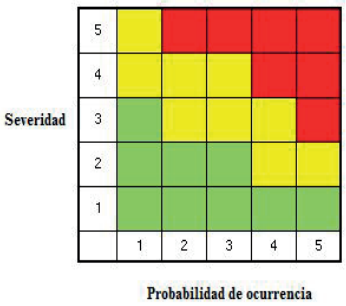
DOW Argentina, Bahia Blanca, (B8000), Argentina

cdzurlo@dow.com

Resumen

Aplicación de tecnología e innovación con el fin de reducir riesgo, aumentar la eficiencia y reducir costos en los procesos de mantenimiento de la industria petroquímica, específicamente en Ingreso a Espacios Confinados (IEC).

Palabras clave: Innovación, tecnología, Industria.



1 Identificación de la oportunidad, Tareas de riesgo

En la labor diaria de la producción química y petroquímica existen gran cantidad de tareas que suponen un peligro para la persona. Desde lo más ínfimo, como ser una caída al caminar, cuyo resultado puede ser una torcedura de tobillo o un raspón en el cuerpo, hasta el peligro que implica trabajar en un espacio confinado dónde una fuga de Nitrógeno provocaría la asfixia de la persona, cuyo resultado final será la muerte.

Aclaramos dos conceptos claves para fundamentar la necesidad de lo expuesto en este trabajo, hablamos de *peligro y riesgo*. El peligro es una condición o característica intrínseca que puede causar lesión, enfermedad o muerte, en cambio el riesgo es la combinación de la probabilidad y la consecuencia de no controlar el peligro en cuestión.

A fines prácticos podemos categorizar las tareas de menos a más riesgosas en función del producto mencionado, siendo "1" la tarea cuyo peligro es menos severo y/o menos probable, y 5 la que tiene mayor consecuencia y/o mayor probabilidad. Como se visualiza en el cuadro siguiente.

Severidad		Probabilidad	
5	Accidente grave, peligro de muerte, gran fuga de tóxicos o combustible a la atmósfera. Impacto a la comunidad	5	extremandamente probable
4	Accidente registrable grave, fuga óxica a la atmósfera. Incidente de proceso.	4	muy probable
3	Accidente registrable, fuga a la atmosfera de combustible o llama	3	probable
2	primeros auxilios, fuga a la atmosfera menor de combustible	2	poco probable
1	accidente precautorio, nada severo.	1	Muy poco probable

Hartas conocidas las consecuencias negativas de un evento de seguridad en la planta, no entraremos en los detalles de por qué es necesario analizar y mitigar los riesgos.

DOW en particular cuenta con miles de empleados, realizando tareas de similares características en todo el mundo y la forma de categorizar las tareas para alertar sobre los potenciales riesgos que conllevan, ha sido a través de los Estándares Críticos para la Vida. Existen dentro de la compañía ocho estándares críticos:

- Ingreso a espacio confinado
- Trabajo eléctrico
- Trabajo en altura
- Trabajo en caliente
- Hidrolavado y lavado a presión
- Aislación de fuente de energía
- Apertura de líneas y equipos
- Permiso de trabajo seguro

Entendemos que al momento de realizar una tarea que encaja en una de las categorías mencionadas se debe tomar recaudos particulares (detallados en cada estándar). Además, éste listado es un excelente punto de partida para definir aquellos aspectos dónde plantear un plan de trabajo con el objetivo de reducir riesgos.

Si bien nuestra organización, y la industria en general, se encuentra en constante mejora de todos los aspectos que hacen a la seguridad y a la implementación de medidas innovadoras, en este trabajo en particular se presentará un caso de éxito aplicado para reducir la tasa de eventos en *ingresos a espacio confinado (IEC)*, disminuyendo la cantidad de horas de exposición.

A grandes rasgos, identificamos como *espacio confinado* a un espacio suficientemente amplio para que una persona ingrese y trabaje, pero,

- Con ingreso y/o salida limitada o dificultosa,
- No diseñado para estar ocupado continuamente,
- Cumple al menos una de las siguientes condiciones,
    - Contiene o tiene potencial de contener una atmósfera peligrosa,
    - Contiene un material que tiene el potencial de envolver a quien esté dentro,
    - Tiene una configuración interna en la cual una persona podría quedar atrapada o asfixiada o,
    - Contiene otro peligro reconocido

Vale aclarar que en toda la industria química, petroquímica y afín vamos a encontrar gran cantidad de equipos, como ser calderas, pulmones, piletas, intercambiadores, hornos, etc., que, por cuestiones de seguridad de proceso, mantenimiento, inspección y regulaciones, requieren que se realicen tareas en su interior.

Existen al menos dos tipos de medidas a considerar para reducir riesgos:

1.1 Colocación de barrera física o uso de elemento de protección personal.

Instalar barreras que impidan el contacto entre la persona y la fuente de un riesgo. El peligro sigue estando, se disminuye o anula, la probabilidad de que tenga lugar el accidente o las consecuencias de este. El condicionante ante este tipo de medidas es que una mala implementación podría derivar en un evento, ya que la fuente del peligro sigue estando.

Ejemplo aplicado: Colocación de placas.

Previo ingreso a un espacio confinado, se colocan placas en las cañerías que conectan al equipo en cuestión con el resto del proceso, con el objetivo de asegurar que ningún fluido no deseado (como ser N2, Etano, Etileno, o cualquier producto nocivo) pueda ingresar mientras una persona se encuentra dentro trabajando.

Una placa mal colocada, o una válvula mal cerrada y/o con fuga, puede derivar en un evento de seguridad.

Ejemplo aplicado: Uso de equipo autónomo de respiración.

Implica agregar un grado de complejidad para realizar la tarea, mayores tiempos, costos y mayor exposición al peligro con menor riesgo.

.

1.2 Eliminar la tarea o modificar la forma de realizarla.

Modificar la naturaleza del sistema y/o el procedimiento de ejecución de tal forma que la tarea en cuestión deje de ser necesaria o se ejecute de otra manera y por lo tanto el peligro deje de existir.

Ejemplo aplicado: Uso de equipo autónomo de respiración.

Durante los últimos años en el complejo de Bahia Blanca se comenzaron a utilizar robots comandados a distancia para realizar cierto tipo de inspecciones, de esta manera se evita el ingreso a espacio al espacio confinado.

2 Plan de acción

Como ya se mencionó, el objetivo es reducir al mínimo e indispensable las horas hombre de IEC. Por lo tanto, se hizo necesario avanzar con medidas de tipo 1.1.2, es decir no agregar una barrera de protección, sino que modificar la forma de realizar la tarea o la tarea en sí misma. Para lo cual presentamos y llevamos adelante dos proyectos.

2.1 Uso de robots para realizar inspecciones

Se han utilizado desde 2018 y los resultados han sido positivos. Gran cantidad de inspecciones dónde implicaba que una persona debía ingresar a un equipo, se han reemplazado por el ingreso de un robot.

Principalmente utilizando tres modelos, en primer lugar “el Crawler” robot simil carro, con capacidad de imantarse (a superficies ferromagnéticas) y moverse dentro del equipo, incluso de manera vertical (como se observa en las fotos 1 y 2) posee cámaras de alta definición y se puede inspeccionar en vivo (ver foto 3). El único condicionamiento es que las paredes del equipo deben estar con cierto grado de limpieza para que pueda imantarse y, por supuesto, requiere a alimentación eléctrica.

Foto 1

Foto 2

Foto 3

En segunda instancia contamos con la cámara “spectrum” que es básicamente una cámara de alta definición con alcance 360° (manejable a distancia) y la capacidad de ingresar al equipo a través de una extensión manual.

En tercer y último puesto, el uso de drones para inspección. Cubiertos con una jaula de fibra de carbono, incluye linterna led y capacidad de filmar en HD, cámara termográfica, además de poder ver en vivo a través de computadora.

2.2 Uso de cámaras vigía para evitar persona extra dentro de EC.

Según estándares de DOW, siempre que una persona esté dentro de un espacio confinado debe ser monitoreada; hasta la implementación del uso de cámaras, esto se hacía a través de un observador, o una cadena de ellos en caso de ser necesario, estando el último observador fuera del espacio confinado.

En la actualidad se cuenta con dos cámaras conectadas por cable a un monitor. De esta forma el vigía externo observa a las personas ubicada en el interior, a través de un monitor. Las cámaras cuentan con una base magnética que les permite adosarlas a cualquier superficie ferromagnética.

El sistema de Video está formado por 2 cámaras Hikvision IP con resolución Full HD, vinculadas a un NVR Móvil Hikvision, con un monitor led de 12".

El sistema NVR Móvil se encuentra asimismo instalado en una maleta estanca con ruedas, construida en plástico de alto impacto, donde a su vez se encuentra el monitor led de 12". El sistema se alimenta con una batería de Gel de 12v-17Ah, la cual provee una autonomía aproximada de 6 hrs. Sobre el exterior de la maleta se encuentran los jack industriales de RJ45 uno para cada cámara y un conector para el cargador de la Batería.

Medidas del gabinete: medidas externas 56 cm x 35cm x 23cm, medidas internas 50cm x 28cm x 19cm.

Las cámaras Ip mini Domo se instalaron sobre una caja estanco de 10 x 10 cm, cuya base posee un imán de 8 cm de diámetro por 3 de espesor, con capacidad de soportar 1,5 Kg de fuerza. En el exterior de la caja se colocó un Jack industrial Rj45, desde donde se conecta el cableado hasta la NVR.

Como medida de seguridad adicional las cajas de las cámaras poseen un cable de acero con ganchos de apertura rápida, para asegurar la cámara a la estructura. Esto es pensando en el momento de la instalación del cableado, se realice una fuerza mayor a la soportada por el imán y la cámara no caiga al piso quedando colgada de la estructura.

Para conectar las cámaras al gabinete se cuenta con 4 cables UTP exterior doble vaina de 30 metros de largo con fichas RJ45 industriales en cada extremo (hembra y macho), esto permite extenderlo de ser necesario. Se incluye un cargador de batería externo, con indicadores de estado de la batería y la opción de carga rápida.

Un punto de relevancia consiste en que a pesar de que existe en el mercado internacional este tipo de equipamiento, optamos por el diseño, configuración, armado y provisión en conjunto con un proveedor local, logrando un producto apto para el fin que fue pensado, a un valor substancialmente menor al del equipo importado (un 20% con respecto al valor del importado)

3 Resultados

Consideramos que los resultados fueron óptimos, porque se cumplió, y sigue cumpliendo cada vez que se utiliza un equipo de los mencionados, el objetivo principal que es evitar horas hombre dentro de espacio confinado.

Además, vale mencionar que de manera indirecta la organización se benefició de otra forma, más imperceptible que la primera, pero en el mismo escalafón de importancia: crecimos en creatividad, en capacidad de innovar, de asumir el riesgo que implica utilizar nuevas herramientas, en salir de la zona de confort, analizar nuevas ideas/formas/métodos, lo cual involucra que quienes fueron y son parte de este proceso cambiaron y cambiarán para siempre su manera de razonar ante futuros desafíos, articulando además con proveedores de servicio y tecnología locales, potenciando el desarrollo en conjunto. Esto, junto a otros valores, es lo que ayuda a las organizaciones como la nuestra a crecer, a mejorar, a adaptarse, a producir más eficientemente y con mayor seguridad.

Indice de Calidad de Vida Laboral

Horacio Cardozo, Jesica Pereyra Rodríguez

Husal S.A., CEEUIBB; Bahía Blanca, 8000, Argentina

horaciocardozo@husal.com.ar

Breve reseña de la empresa

Husal Construcciones y Servicios, es una empresa radicada en Ingeniero White, Bahía Blanca; dedicada a prestar servicios de reparación y limpieza de recipientes sometidos a presión y tanques, fabricación de cañerías y estructuras metálicas, armado y desarme de andamios, servicio de hidro-grúa, construcción de obras civiles, servicio de limpieza de edificios, oficinas y mantenimiento de espacios verdes, servicio de hidro-lavado de alta presión, hidro corte e hidro demolición.

La empresa comenzó sus actividades en la Argentina en 1982, como una empresa de construcciones y servicios. La creciente demanda de servicios complementarios para dichos proyectos llevó a la empresa a ampliar sus actividades, diversificándolas en toda la Argentina.

La Misión de Husal Construcciones y Servicios S.A. es: "Desarrollar, construir y brindar servicios al entorno empresarial e industrial".

La Visión de Husal Construcciones y Servicios S.A. es: "Ser líder: la primera opción del Cliente, en servicios de construcción y desarrollo de proyectos empresariales e industriales".

Desde sus inicios Husal ha sido una empresa comprometida activamente con la mejora continua del ámbito comunitario, el crecimiento sustentable y el cuidado medioambiental. A partir de estas premisas organizacionales, se comienza a trabajar sobre el concepto de RSE.

Para llevar adelante estos principios, la Dirección participa en forma activa, con el fin de fortalecer la integración humana y profesional de toda la Organización, como base para el mantenimiento y la mejora continua del Sistema de Gestión Calidad, Medio Ambiente, Seguridad y Salud en el Trabajo, así como también proveer los recursos necesarios para asegurar que todo el personal propio y contratado puedan cumplir con los principios de la presente política.

Problemática detectada

Con base en la productividad que venía manteniendo la empresa hasta el año 2015, la misma se vio en la necesidad de medir de forma cuantitativa, a través de un Índice, cuán motivados estaban sus empleados. De esta manera consideraban que, aplicando acciones incentivadoras y motivadoras, permitirían que el trabajador aumentara su productividad o mejorara su trabajo.

El índice que construyeron, llevó el nombre de Índice de Calidad Vida Laboral (ICVL), y constaba de una serie de preguntas organizadas de modo tal que se obtuvieran resultados específicos para los siguientes 6 ejes:

- Caracterización demográfica del personal
- Distribución del personal, según actividad realizada en la empresa
- Situación personal con el trabajo
- Características laborales
- La empresa
- Vida personal

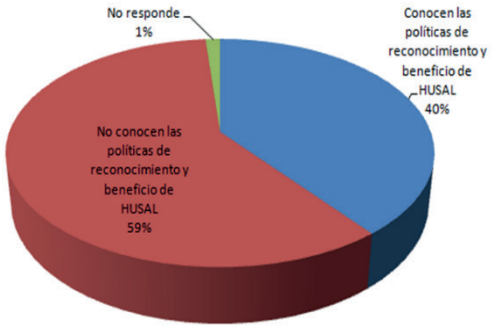
Solución implementada:

Una vez realizada la primera parte del índice, la Dirección de la empresa junto a los asesores externos, se reunieron para definir las acciones motivadoras que generarían el aumento de productividad en el empleado, teniendo bien en claro que las mismas no serían del tipo incentivo monetario, ya que lo que se buscaba era generar en el trabajador de Husal, un compromiso y sentido de pertenencia para con la empresa que traspasara las implicancias económicas.

Dentro de las acciones que se diseñaron, se destacaron en su puesta en marcha las siguientes:

- El proyecto “Mi Casa”: se brindaron materiales de construcción y mano de obra voluntaria para aquellos empleados que tenían falencias en sus viviendas o que las mismas repercutían de forma negativa en su calidad de vida.
- Torneos de futbol: se organizaron torneos de futbol para los empleados interesados buscando que los mismos trabajaran en equipo para un fin común externo del ámbito laboral, pero que sentaría una base para futuras actividades.
- Capacitaciones, coaching en resolución de conflictos: cuando se realizó la primera etapa del relevamiento, la empresa notó que una importante cantidad de empleados se veían interesados en que la Organización le brindara las herramientas para resolución de conflictos dentro del ámbito laboral, para

ello se les otorgó la posibilidad de formar parte de capacitaciones que abarcaran los diferentes ámbitos de interés en ese sentido.



Resultados obtenidos

Una vez llevado a cabo las "acciones motivadoras", se volvió a realizar una etapa de medición del Índice con la premisa de buscar resultados o diferencias comparativas respecto a la primera medición.

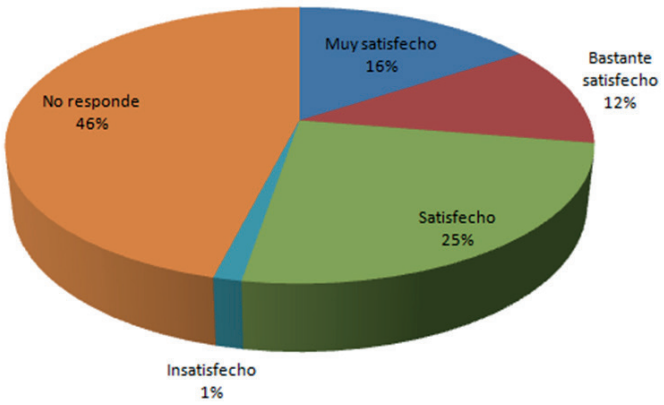
Los resultados y análisis realizados llegaron a la conclusión de que las acciones aplicadas, si bien aportaron un grado de incentivo e interés en el empleado que participó de ellas, no se produjo el "efecto contagio" que se esperaba para el resto de los trabajadores. Es decir, la medición del índice continuó en valores similares a los obtenidos en la primera etapa.

Representación grafica de algunos de los aspectos más relevantes encuestados.

Más de la mitad de los empleados (**59%) manifiestan no conocer las políticas de reconocimiento y beneficio de HUSAL.**

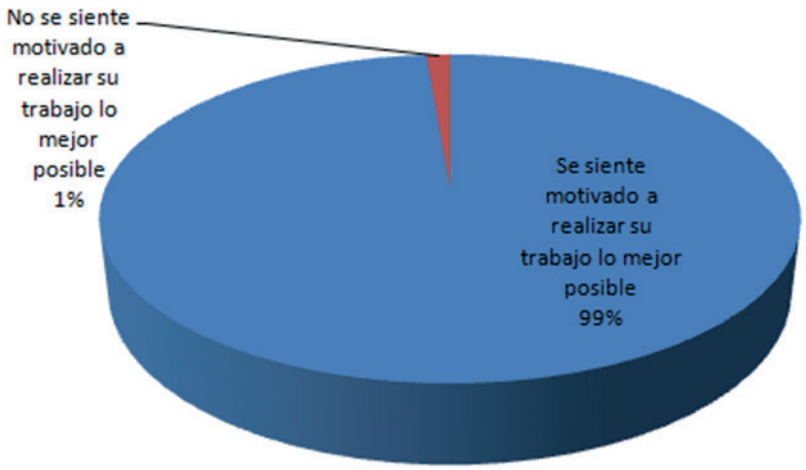
Quienes las conocen (30 respuestas), lo hicieron de diferentes maneras:

- *"Las conocí mediante charlas o avisos y folletos informativos realizados por Husal."*



- *"A través del encargado/supervisor o técnicos".*

- *"Porque en el obrador hay un cartel con las políticas".*



- *"Por el puesto que ocupo, tengo mucho contacto con los puestos gerenciales y ellos transmiten su filosofía".*

- *"Por experiencia propia y también al verlo plasmado a determinados empleados".*

Entre quienes fueron reconocidos o beneficiados, es alto (53%) tienen un alto nivel de satisfacción con lo que han recibido.

Prácticamente el total de los empleados se siente motivado a realizar su trabajo lo mejor posible.

Comentarios finales

Independientemente de los resultados obtenidos a través de la medición del ICVL, la empresa tiene, dentro de sus objetivos principales, los siguientes:

- "Optimizar el clima laboral brindando herramientas y capacitación para la toma de decisiones, la comunicación efectiva, la resolución de conflictos y el trabajo en equipo. Fortalecer la pertenencia y la capacidad de evaluar los procesos laborales. Brindar espacios para el esparcimiento y la mejora de la calidad de vida".
- "Fomentar la participación en el Voluntariado Corporativo Motivar a todo el personal propio y contratado, así como clientes y proveedores a comprometerse en acciones de RSE que desarrolla la empresa. Fortalecer el compromiso con el cambio social y el cuidado medioambiental".

De esta manera queda clara la postura de Husal Construcciones y Servicios S.A. para con sus empleados y la calidad de entorno laboral a la que aspiran.

Adaptaciones a las nuevas demandas y tendencias

Gustavo Lari

Sueño Austral, Bahía Blanca, 8000, Argentina

gustavolari@suenoaustral.com.ar

Breve reseña de la empresa

Sueño Austral es una joven empresa que desde sus inicios, en 1997, representa a Piero SAIC en la provincia de La Pampa, sur de la provincia de Buenos Aires y en todo el sur Argentino. En un primer momento, alquilando un galpón de 250 metros cuadradosse presentó a Piero un proyecto para realizar la representación de su marca en tres etapas bien marcadas, que tenían que ver con el territorio. En primer lugar, todo el Valle hasta Esquel, en segundo lugar, el sur hasta Comodoro Rivadavia y en tercer lugar el sur hasta Ushuaia.

Se comenzó, como toda empresa familiar, haciendo todas las tareas (viajes, administración, depósito, reparto, etc.) y con el correr de los años no sólo creció como empresa, sino logró ser reconocida como referentes en el mercado. Hoy cuenta con un depósito de 3.000 metros cuadrados, 500 metros cuadrados de oficinas y showroom, 4000 de fábrica, y un staff de más de 40 colaboradores. La firma nunca perdió de vista que es una empresa de servicios, que masallá de la venta de mercadería se debe al cliente. Su evolución indica que marcha por el buen camino.

Con el avance del tiempo los directivos se dieron cuenta que existía un potencial en toda la zona para poder empezar a fabricar productos relacionados con el rubro en el que estaban trabajando, y además empezar a ser protagonistas principales en la historia de nuestra empresa. Es por esto que se decidió ampliar el campo de negocios y fabricar juegos de living, guata, vellón, sábanas, acolchados, almohadas, matelaseados, etc., lo que hizo que se pudiera tener una mayor participación dentro de los clientes y en el mercado en general.

Problemática detectada

Con el correr de los años los directivos se dieron cuenta que era fundamental para la evolución de la empresa familiar dar un salto de calidad y mejorar en los distintos tipos de problemas que lógicamente fueron apareciendo juntos con el crecimiento. La distancia entre los clientes y el elevado valor de los fletes al sur hacen que el despacho de la mercadería sea difícil y costoso. Teniendo en cuenta que la mayoría de

los transportes están en Buenos Aires, enviar la mercadería de Bahía Blanca es un poco más complicado.

Desde que empezaron a despachar los juegos de living, se dieron cuenta que el embalaje tenía que ser muy bueno y que el transporte no tenía que hacer trasbordo. Por ejemplo, en un camión entran 35 juegos de living y la distancia a Ushuaia desde Bahía Blanca es de 2450 km., es decir es muy alta la incidencia del costo de transporte. Por lo expuesto, se decidió empezar a cambiar e innovar para que poco a poco mejoren los resultados.

Solución implementada

El primer cambio fundamental en la empresa fue la compra de un camión propio para mejorar la entrega. En poco tiempo se amplió la flota y hoy cuentan con tres camiones para el reparto de su propia mercadería. Además, tercerizaron los viajes desde Buenos Aires a Bahía Blanca pero el reparto interno quedó en manos de la empresa. Rápidamente tuvieron un crecimiento en las ventas dado que la incidencia del flete fue mucho menor, y al completar el camión con varios clientes la entrega se hizo con mayor frecuencia. Esto también mejoró la participación de Sueño Austral en los clientes dado que dejaron algunas marcas para inclinarse en esta.

La innovación más significativa fue la de diseñar un juego de livingtotalmente desarmable, que entre en cajas, sea fácil de armar conteniendo sus propias herramientas, que tenga la opción de puerto USB para carga de celulares y tablet, que se pueda cargar en un camión con autoelevador y se pueda estibar en estanterías.Después de varios meses de trabajo se logró un producto de buen precio, que se ajusta a la calidad pretendida, fácil de armar y estandarizado en su producción. Esto mejoró mucho el costo de flete dado que se pudo duplicar la cantidad de juegos de living trasladados.

Se confeccionó un tutorial en video para el armado, que reemplaza al típico manual de instrucciones, y se grabó un spot publicitario en uno de sus principales clientes, la Cooperativa Obrera, para dar sentido práctico a todo lo que pregona el producto. Además, se registró la marca LIVING-BOX - TU LIVING EN CAJA.

Finalmente, la empresa tiene como proyecto concretar la compra de una máquina para fabricar el modelo de almohadas más vendido, con lo cual podría duplicar la fabricación y sobre todo dejar libre la máquinade cardado para continuar creciendo en la venta de guata, vellón, y en la fabricación de acolchados y matelaseados. Debido a la situación actual es un proyecto que quedará para más adelante.

Resultados obtenidos

La empresa considera muy favorables los resultados de las mejoras implementadas, particularmente en relación al nuevo juego de living desarmable. Los mismos se detallan a continuación:

- Con la compra de camiones propios aumentaron las ventas y mejoró la calidad en las entregas bajando considerablemente el costo de flete a los clientes.
- En un camión se pueden cargar el doble de productos, por lo que bajó considerablemente el costo de flete. Para un cliente de Río Gallegos, por ejemplo, el flete disminuyó por lo menos al 50%.
- Se pueden apilar los juegos de living en estanterías de a 10 cajas sin dañar la espuma.
- El armado es sumamente fácil, a tal punto que una pareja sin experiencia lo puede hacer en menos de 30 minutos.
- En los edificios de departamentos, donde los juegos de living, en especial los esquineros, no pueden entrar o subir por escaleras, los mismos pueden ser subidos por ascensor o escalera gracias a su embalaje en cajas.
- El puerto USB que da la posibilidad de cargar dispositivos mientras se descansa o se mira TV generó un impacto muy importante en el posicionamiento del producto.

Comentarios finales

La empresase encuentra sumamente conforme con las mejoras implementadas, particularmente con la innovación realizada en el juego de living desarmable. Pese a que no se pudo realizar un lanzamiento del producto como lo tenían planificado, se logró posicionar el producto y los comentarios de los clientes son positivos. Se prevé realizar el lanzamiento cuando se retorne a una situación más normal, para no perder trascendencia.La idea de la empresa es seguir creciendo y expandiéndose en la región con locales.Buscan agrandar la fábrica y llegar a tener 20 locales entre propios y franquiciados.

La incertidumbre y las duras condiciones productivas dificultan la marcha de los proyectos pero no los detienen. En este sentido, la firma siempre fue optimista y apostó a ser protagonista de su propio desarrollo.

Herramienta de Gestión – Pool de Contenedores Vacíos para ordenes MPC

Joaquín Alencastre Cordi, Augusto Ferraro

Dow Chemical Company, Bahía Blanca, Argentina

Jalencastrecordi1@dow.com , AFerraro@dow.com

Resumen.
El presente escrito tiene como objetivo describir la herramienta de gestión utilizada para definir las acciones a realizar con respecto a la gestión del pool de contenedores vacíos, que luego se utilizarán para ordenes de exportación marítimas.
Estos contenedores poseen cierta cantidad de días "libres" (en general, 21 días), que una vez superados, comienzan a generar costos diarios de "Demurrage/Dentention", los cuales son abonados una vez que los contenedores ingresan nuevamente a una terminal portuaria. Por eso, es fundamental contar con un pool de vacíos adecuado, que permita cumplir con la demanda, aunque sin sobredimensionarlo, ya que si no son utilizados en el futuro próximo, se traducirán en extra costos.
Esta herramienta de gestión (la cual está basada en un solver de modelo lineal), propone una serie de acciones a tomar para disponer del número apropiado de contenedores vacíos. En función de la disponibilidad de contenedores y de la demanda confirmada y proyectada de las próximas semanas, la herramienta selecciona las acciones más eficientes para incrementar o disminuir el pool según corresponda.

Palabras clave: Supply Chain, Logística, MPC, Vacios, Navieras, Detention, Eficiencia.

1 Gestión del pool de vacíos

1.1 Operación Histórica y Oportunidad de Mejora

La operación de despacho de ordenes de exportación marítima cuenta con numerosas particularidades, una de ellas consiste en la necesidad de contar con el producto consolidado en un contenedor determinado, que luego será trasladado hasta una terminal portuaria y embarcado hasta destino. Por eso, es que Dow cuenta con cierto inventario de contenedores vacíos de distintas navieras, que luego utilizará para estas órdenes.

Históricamente, el pool de vacíos se va rotando a medida que los contenedores llenos ingresan a la terminal. La gran mayoría de los traslados se realizan en tren, por lo que

el mismo vagón que se utiliza para enviar el contenedor consolidado con producto, luego se utiliza para retornar el vacío desde la terminal.

Sin embargo, el dimensionamiento del pool de vacíos no se trata de algo trivial, si no que requiere de análisis. Sobredimensionar el numero de contenedores a la espera de producto para embarcar no resulta eficiente en términos económicos ni operativos (falta de espacio), mientras que subdimensionarlo implica dejar de cumplir con la demanda.

Centrándonos en los términos económicos, es importante resaltar que las navieras conceden cierta cantidad de días "libres" a los contenedores que entregan a sus clientes. Una vez que ese tiempo finalizó, se empiezan a generar costos diarios de "Detention", que luego serán abonados cuando el contenedor retorne a alguna terminal portuaria.

Por eso, nos pareció oportuno diseñar una herramienta que permita gestionar de manera integral la disponibilidad de vacíos en la planta de Bahía Blanca. De esta manera, acercarnos al punto optimo con respecto al pool, y disminuir el tiempo humano dedicado a la toma de decisiones respecto a este tópico.

1.2 Herramienta de Gestión de Vacíos

La herramienta de gestión (desarrollada bajo el modelo de Solver Líneal) incluye información con respecto al pool actual de cada una de las navieras, demanda confirmada y proyectada en el tiempo de cada una de ellas, cantidad de contenedores en tránsito retornando a la planta y la programación de envíos de los contenedores a cada una de las terminales. Así, tenemos un estado inicial, en el cual, a partir del Stock Actual, se suman los ingresos programados de vacíos y se resta la necesidad confirmada y proyectada de los mismos. Aquí, es probable que el pool de vacíos no sea suficiente o sea mayor al necesario, por lo que se deben tomar acciones para alcanzar el estado deseado.

El objetivo de la herramienta es claro, disponer de un pool de vacíos suficiente para cumplir con la demanda, pero de manera óptima. Por eso, es que se define un "Stock Objetivo" semanal de vacíos, que se define como la necesidad de la semana próxima, más la mitad de la demanda proyectada para la semana posterior. Así mismo, para evitar el sobredimensionamiento del pool, se define una restricción que limita la tolerancia de disponibilidad de vacíos sobre el estado óptimo.

Por otro lado, las acciones necesarias para llegar a este Stock Objetivo son muy variadas (dependen de cada naviera, de la terminal utilizada por la misma, por la necesidad en el tiempo de los contenedores, etc.) y como es de esperarse, tienen diferentes costos asociados. A los efectos de la herramienta, se definieron costos cualitativos para cada una de las posibles acciones, de manera de jerarquizar las opciones que nos permitirán cumplir con nuestro objetivo. Así, la herramienta busca minimizar la función objetivo (sumatoria de acciones por el costo de cada una de ellas) reflejando las prioridades operativas. Luego, existen diversas restricciones que se definen en función de la operación particular de cada destino, naviera y terminal portuaria, que obviamente limitan la resolución de cada estadío.

Cabe resaltar que las acciones propuestas para cada naviera, puede tener consecuencias sobre el pool de otra. Por eso, es fundamental definir las variables de decisión de manera simultanea para alcanzar la solución óptima.

Finalmente, la herramienta provee una serie de acciones que definen el plan de acción semanal con respecto a la gestión del pool de vacíos. Estas actividades son informadas a cada uno de los eslabones de la cadena y sus respectivos responsables en una reunión semanal.

1.3 Actores Intervinientes

En el proceso de gestión del pool de vacíos hay diversos actores involucrados, a saber:

- Analista Logístico: Responsable de gestionar el proceso y consolidar la información de los distintos eslabones, es quien define el plan de acción semanal con respecto al pool de vacíos de cada naviera.
- Operador Logístico Bahia Blanca: Responsable del consolidado y despacho de contenedores a exportar, además coordina acciones en función del plan definido.
- Operador Logístico Bs As: Responsable de la gestión de retorno de contenedores (o no) desde terminales en GBA, en función de las acciones definidas en el plan semanal.
- Freight Forwarder: Encargado de gestionar los bookings para las ordenes MPC y ordenes de retiro de vacíos de cada una de las terminales.

1.4 Implementación

Dado el panorama mundial de incertidumbre, de manera conservadora DOW había decidido incrementar fuertemente el pool de vacíos en Bahia Blanca, de manera de asegurarse la posibilidad de abastecer su demanda, aunque asumiendo el riesgo de un incremento importante de los costos de Detention.

Así, la herramienta de gestión se comienza a implementar a fin de Mayo de este año, con el claro objetivo de gestionar el pool de vacíos de una manera más eficiente. Además, se coordinan reuniones semanales de seguimiento y definición de plan de acción, en la que participan todos los eslabones de la cadena de suministro.

Los resultados de la gestión integral de vacíos se reflejaron rápidamente en la disminución de los costos de Detention abonados. A partir de la implementación de las estrategias mencionadas, los extracostos afrontados en términos de Detention disminuyeron a un tercio, con respecto al promedio de los primeros cinco meses del año (ver Fig. 1).

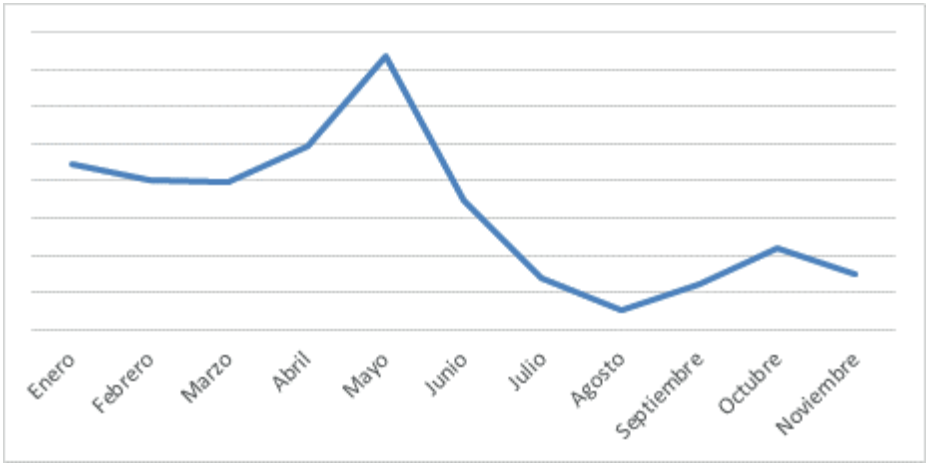

Fig 1. Distribución de costos por Detention en 2020.

Desarrollo de un Caso de Uso de Industria 4.0 en una Planta de Producción de Aguas y Gaseosas

Resumen

Existen numerosos trabajos que describen y recopilan las tecnologías utilizadas en el contexto de la Industria 4.0 y sus beneficios. Sin embargo, los trabajos que exponen casos de uso concretos son más escasos. El objetivo del trabajo es presentar los resultados preliminares del desarrollo de un caso de uso de Industria 4.0. La metodología se basa en el modelo de cinco etapas. Asimismo, la metodología incluye entrevistas a expertos de la planta y encargados de Planeamiento, la observación directa, y el análisis de documentos de la planta. Se considera una planta de producción de aguas y gaseosas. Se describe el relevamiento preliminar de los procesos productivos de la compañía, donde se podrá apreciar brevemente el análisis de las líneas productivas de la compañía, las partes integrantes, requerimientos productivos, áreas intervinientes y principalmente permitirá la detección de problemas actuales, potenciales y futuros. Además, se incluye la evaluación de madurez sobre la aplicación de tecnologías de la Industria 4.0 en el área de Producción. Finalmente, a partir de los resultados preliminares se plantea el trabajo futuro en el desarrollo del caso de uso.

Palabras clave: Industria 4.0, Modelo de Madurez Industria 4.0, Producción.

1 Introducción

La Industria 4.0 implica una transformación a partir nuevas tecnologías industriales, tales como robots avanzados, manufactura aditiva, realidad aumentada, big data, computación en las nubes, entre otras [1], [2], [3]. La revolución en la industria trae consigo impactos significativos en la producción, así como un incremento en la eficiencia de la utilización de recursos, y mayor capacidad para integrar y aumentar la flexibilidad en las líneas de producción. La penetración de las tecnologías de Internet en la Industria 4.0 puede ir más allá de los procesos de fabricación incluyendo el desempeño logístico dentro de una Red Global de Producción. Una Red Global de Producción se refiere a un conjunto de entidades de producción distribuidas (globalmente) que contribuyen a la creación de valor.

Con referencia a la República Argentina, la consultora The Boston Consulting Group [4] elaboró un informe basado en un relevamiento entre 78 ejecutivos de 66

grandes empresas industriales de diferentes sectores. Se indica que si bien los ejecutivos conocen las tecnologías pocas empresas invirtieron en ellas. Solo el 30% indica que en su empresa implementaron una iniciativa concreta. El mayor grado de implementación se observa en las tecnologías relacionadas con la seguridad e infraestructura de datos. Sin embargo, solo el 9% indica que actualmente ha implementado tecnologías de fábricas inteligentes, control de la producción y diseño de fábrica digital. Las principales barreras para su adopción son la falta de personal calificado (70% de las respuestas), la incertidumbre respecto al retorno económico de las inversiones (65%), y la resistencia al cambio y la innovación (64%).

Si bien existen numerosos trabajos que describen y recopilan las tecnologías utilizadas en el contexto de la Industria 4.0 y los beneficios [5], [6], los trabajos que exponen casos de uso concretos son más escasos. Este trabajo tiene como objetivo desarrollar un caso de uso de Industria 4.0 para un área organizacional que mejore la calidad de los productos y el desempeño logístico. Se trata de un proyecto en desarrollo y en este trabajo se exponen los resultados preliminares.

El trabajo está organizado de la siguiente forma. A continuación, se describe la metodología. En la sección 3 se resume el marco de trabajo utilizado. En la sección 4 se presentan los avances y en la sección 5 se incluyen las conclusiones preliminares y el trabajo futuro.

2 Metodología

El objetivo del trabajo es desarrollar un caso de uso de Industria 4.0 para un área organizacional que mejore la calidad de los productos y el desempeño logístico. Se trata de una planta de producción de aguas y gaseosas. Por su tamaño, se considera grande, o gran empresa, de acuerdo a la clasificación de empresas en Argentina, según la Secretaría de Empleo [7] en la cual se indica que si la organización cuenta con más de 200 empleados permanentes, le corresponde la categoría más alta. Para la Unión Europea [8], en base a al tamaño y complejidad de la empresa, esta se clasifica como mediana dado que la valuación de sus activos no la ubicarían en el escalón más alto. A efectos de desarrollar el caso de uso en la industria 4.0, se siguen las etapas de trabajo propuestas por Peukert et al. [9] para pequeñas y medianas empresas. En este caso la unidad de análisis será la planta. La metodología se basa fundamentalmente en las entrevistas a expertos de la planta (Gerente de producción, Jefe de producción, Jefe de mantenimiento, supervisores de producción y encargados de Planeamiento/Cadena de Suministros), la observación directa, y el análisis de documentos de la empresa tales como manuales de procedimientos.

3 Marco referencial teórico

Peukert et al. [9] observan que las empresas pequeñas y medianas, muchas de las cuales operan como proveedores en redes de producción globales, muchas veces están más atrasadas en la implementación de la Industria 4.0. Los autores proponen un modelo de procesos de cinco etapas que busca hacer uso del potencial de la Industria 4.0 en términos de mayor calidad del producto e indicadores de desempeño logístico

dentro de la red. La propuesta identifica problemas potenciales que impiden una mejor calidad del producto o desempeño logístico, y a partir de esos problemas, se derivan soluciones que aprovechas tecnologías de la Industria 4.0. La propuesta de Peukert et al. [9] se basa en los modelos de procesos de Noehring et al. [10] y Bildstein y Seidelman [11] y extiende el trabajo para aplicarlos en empresas pequeñas y medianas operando en redes de producción global. A continuación, se resumen las cinco etapas propuestas en el trabajo de Peukert et al. [9].

Etapa inicial. El objetivo es identificar problemas potenciales que impiden un incremento en la calidad de los productos y el desempeño logístico. Para el problema identificado y seleccionado se desea desarrollar una solución basada en tecnologías de la Industria 4.0.

Análisis. Para el problema identificado se debe registrar el estado de las cosas para elaborar capacidades clave y debilidades y desarrollar abordajes preliminares de solución. Previo al análisis de los procesos afectados por la red de producción global, se realiza un estudio de las competencias de la compañía con respecto a la Industria 4.0. El estudio se basa en utilizar una herramienta denominada Modelo de Madurez Industria 4.0 para considerar el producto y los procesos de producción. Para los productos, se desea entender en qué medida se puede agregar valor a los productos en base a tecnologías de Industria 4.0. Además, se desea entender el estado actual de los procesos de producción y vislumbrar cómo se podrían optimizar o cómo se podrían reducir los costos utilizando Industria 4.0. Para examinar a los procesos afectados por la red de producción global se utiliza la herramienta Mapa de Flujo de Valor. El objetivo es identificar oportunidades de mejora en términos de control de procesos.

Se utiliza un Modelo de Madurez Industria 4.0 que incluye la perspectiva del proveedor (evalúa a todos los proveedores en la red) y la perspectiva de la red que analiza los niveles de madurez I4.0 de la red como un todo. El foco está en mejorar la calidad del proveedor en términos de sus procesos sin considerar explícitamente la mejora de los productos en términos de usabilidad o valor para el cliente.

Para las debilidades identificadas se pueden analizar sus causas y estructurar dicho análisis utilizando un diagrama de Ishikawa.

Conceptualización. En base a la etapa de análisis, en esta fase tiene como objetivo desarrollar el concepto para un caso de uso I4.0 que contribuya a la resolución del problema seleccionado considerando sus causas. En esta etapa se realiza un taller cuya agenda incluye una motivación para la implementación de I4.0, la presentación de los resultados de las etapas anteriores, un espacio creativo en el cual todos los participantes contribuyen con ideas para resolver el problema en base a I4.0, y la conceptualización del caso de uso.

Realización. La implementación de la solución I4.0 depende de la adquisición de tecnología o know-how a un tercero. Esta etapa da apoyo a la especificación de requerimientos, análisis de potenciales proveedores hasta la selección del proveedor.

Demostración. Esta etapa pretende documentar el caso de estudio a efectos de que sirva de inspiración para otras áreas o empresas.

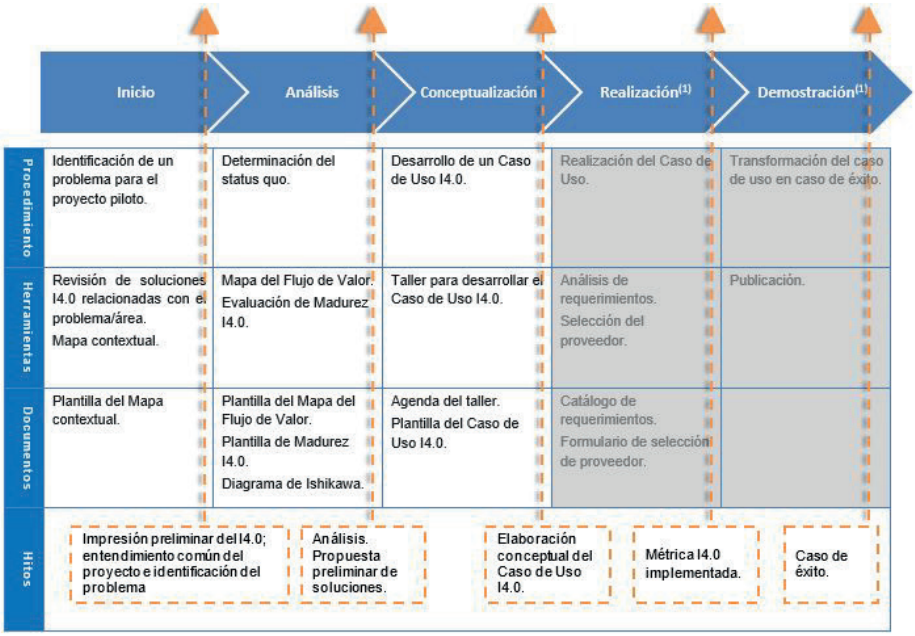

Fig. 1. Etapas para el desarrollo de un caso de uso para implementar una solución basada en Industria 4.0. (1) Etapas no cubiertas en este proyecto. Fuente: Basado en la propuesta de [9].

4 Avance del proyecto

El proyecto se encuentra en la etapa inicial para lo cual se trabajó en un relevamiento preliminar de los procesos. En forma paralela, también se avanzó en la evaluación de la madurez de uso de las tecnologías de Industria 4.0 en la industria estudiada.

En primer lugar, para describir los procesos productivos se entrevistó al Gerente de Producción (entrevista virtual), quien comentó que la elaboración de productos radica principalmente en tres líneas productivas a las cuales denominan de la siguiente manera: Línea 1 (L1), Línea 3 (L3) y Línea 4 (L4). Las mismas son utilizadas de la siguiente manera:

- Línea 1, utilizada principalmente para producir calibres chicos en plástico (PET) de 500 cc, vidrio descartable de 237cc, agua con y sin gas.
- Línea 3, es utilizada para la gaseosa Retornable, tanto en formato vidrio como REF PET.
- Línea 4, la más nueva y tecnológica, utilizada principalmente para calibres más grandes.

La separación de formatos chicos con los grandes entre las líneas 1 y 4, se debe a una cuestión de eficiencia productiva. Esto radica en que, como se menciona anteriormente, la L4 es más nueva, más veloz y mucho más eficiente, con lo cual un lote de calibre inferior se produce mucho más rápido, necesitando realizar muchos cambios en poco tiempo entre un producto y otro (ocurriendo lo contrario en L1).

A continuación, se incluyen las especificaciones generales de cada línea, a fin de detectar problemas potenciales o actuales en los distintos procesos. Las partes integrantes de Línea 1 según el proceso de producción son:

1. Sopladora (ingresan las preformas y salen las botellas).
2. Etiquetadora.
3. Transporte aéreo (lleva la botella etiquetada hasta la entrada de la llenadora a gran velocidad a fin de enfriar el plástico).
4. Llenadora (aquí comenta el gerente que existe un "cuello de botella").
5. Capsuladora (coloca la tapa).
6. Inspectora de llenado.
7. Codificadora.
8. Horno y empaquetadora.
9. Paletizadora.

El punto más frágil de esta línea en términos generales en el número 4, la llenadora. Aquí ocurre a menudo un cuello de botella, y es donde, tanto lo que ingresa a la llenadora como todo lo que sale ocurre en un tiempo más rápido que el proceso de llenado. Otra dificultad -además del tiempo que insume la llenadora- es la temperatura, debido a que la bebida que ingresa en las botellas debe estar a una temperatura de 4° C, y para esto, debe existir un equipo con torres de enfriamiento combinada con la utilización de Glicol para obtener la temperatura requerida de manera constante.

El tipo de llenado utilizado en esta línea es Isobárico, es decir, se deben cambiar los picos dependiendo del calibre o sabor a llenar. Esto último insume tiempo entre las distintas producciones. Además, para el formato 237cc que son de vidrio descartable, la tapa utilizada es estilo corona y no plástica como ocurre con el resto de las botellas, con lo cual, adaptar el sistema de capsuladora también demanda tiempo extra de trabajo.

Por último, la sanitización de toda la línea antes y después de una producción es extremadamente sensible e insume mucho tiempo, conocida comúnmente como "CIP" (por sus siglas del inglés Cleaning In Place).

La línea 4 tiene componentes similares para efectuar el proceso productivo, desde la sopladora hasta la paletizadora, salvando algunas diferencias:

- El proceso de llenado es volumétrico en L4 (a diferencia de L1 que es isobárico), con lo cual no se requiere cambiar picos y demás partes de la llenadora al momento de cambiar el sabor o calibre.
- La temperatura de llenado en L4 es de 15 °C y en L1 es de 4° C.

- L4 produce 40.000 litros por hora de producto terminado con 8 personas por turno mientras que L1 produce aproximadamente 15.000 litros por hora con la misma dotación por turno.
- La tecnología utilizada en L4 es superior. La paletizadora es un robot más veloz que manipula y acomoda los paquetes previos al armado del pallet completo.

Respecto a la línea L3, aquella destinada a la producción con envases retornables, es una línea del año 2010, la cual produce un 85% con botellas de plástico (REF PET) y un 15% con botellas de vidrio. Al igual que la línea 1 de producción, el llenado se hace con una metodología isobárica (se desconoce si existe sistema volumétrico para líneas retornables). Las partes de la línea de producción son similares a las de las líneas anteriores, con la diferencia de que no cuentan con una zona de soplado. Los procesos adicionales que se suman son los siguientes:

- Desencajonadora (al principio) que es la que quita las botellas de los cajones.
- Destapadora se encarga de quitar las tapas de las botellas que la tienen puesta.
- Cadena transportadora con sensores para detectar olores o líquidos fuera de especificación (descartando automáticamente los envases que no se encuentran en condiciones óptimas).
- Lavadora industrial para higienizar las botellas.
- Llenadora.
- Encajonadora (al final) coloca las botellas llenas en los cajones plásticos.
- Paletizadora.

Es una línea “más lenta” en términos de producción, tiene una demanda productiva de alrededor de 25000 litros por hora aproximadamente (funcionando de manera constante) y requiere por lo menos entre 10 y 12 personas para monitorear y llevar a cabo el proceso de elaboración.

El CIP y cambio de picos es un proceso muy lento, y demora algunas horas poder dejarla en condiciones para cambiar el sabor o calibre de la siguiente producción.

En resumen, los problemas claves detectados durante las primeras entrevistas y la observación directa son los siguientes:

- Llenadoras: en alguna línea es muy lenta, sea por método de llenado o por la lentitud en hacerlo. Se debe considerar que, si este punto se logra realizar de manera más rápida y eficiente, se requerirá que tanto los pasos anteriores como los posteriores a la llenadora, también tendrán que aumentar su eficiencia para que el cuello de botella no se genere en otro punto de la línea.
- Temperaturas de llenado: La línea 1 requiere temperaturas muy bajas para su llenado. En otras plantas de la misma subsidiaria existen las llamadas líneas Hot Fill (llenado en caliente) aunque a veces depende del tipo de producto a envasar.
- Falta de versatilidad para cambiar de sabores o calibre rápidamente ante demandas decrecientes, recesión y pérdida de poder adquisitivo, donde los lotes de producción deben ser más cortos.

– Sanitización: demanda mucho tiempo lo cual conlleva a mayores costos.

Con respecto a la madurez, solo evaluamos como primera instancia, lo que respecta a la Producción utilizando la herramienta propuesta por Peukert et al. [9]. Esta evaluación, realizada en conjunto con supervisores de producción, integrantes del área logística y un encargado de Cadena de Suministros, pretende diagnosticar cómo se pueden optimizar procesos productivos y de qué manera se podrían reducir costos de producción con la ayuda de Industrias 4.0. El trabajo propuesto por los autores estructura el análisis en seis temas o dimensiones para el sector de Producción: procesamiento de datos en la producción, comunicación máquina-máquina (M2M), redes empresa y producción, infraestructura de Tecnologías de la Información y la Comunicación (TIC) en la producción, interfaces hombre-máquina y eficiencia con pequeños lotes. Se utiliza una escala de cinco niveles (1-5), considerando a 5 como el nivel más alto de madurez respecto a dicho nivel (ver Fig. 2).

Madurez Industria 4.0 – Producción					
Procesamiento de datos en la producción	No hay procesamiento de datos	Almacenamiento de datos para documentación	Análisis de datos para monitoreo de procesos	Evaluación para planificación de procesos/control	Planificación automática de procesos/control
Comunicación M2M	No hay comunicación	Interfaces field bus	Interfaces ethernet industriales	Las máquinas tienen acceso a internet	Servicios web (software M2M)
Red entre la empresa y producción	No hay red entre producción y otras unidades de negocio	Intercambio de información vía correo/telecomunicación	Formatos de datos uniformes y reglas para el intercambio de datos	Formatos de datos uniformes y servidores vinculados entre divisiones	Soluciones TI totalmente en red
Infraestructura TIC en producción	Intercambio de información vía correo/telecomunicación	Servidores de datos en producción	Portales basados en internet con datos compartidos	Intercambio de datos automatizado (e.g. traza de pedidos)	Proveedores/clientes totalmente integrados en el proceso de diseño
Interfaces hombre-máquina	No hay intercambio de datos entre usuario y máquina	Uso de interfaces locales	Monitoreo/control de producción centralizado/descentralizado	Uso de interfaces móviles	Realidad aumentada y asistida
Eficiencia con pequeños lotes	Sistemas de producción rígidos y una pequeña proporción de partes idénticas	Uso de sistemas de producción flexibles y partes idénticas	Sistemas de producción flexibles y diseños modulares para los productos	Producción basada en componentes, flexible de productos modulares dentro de la compañía	Producción basada en componentes, modular en redes que agregan valor

Fig. 2. Evaluación de madurez de para el caso analizado respecto a tecnologías 4.0. Fuente: Elaboración propia utilizando la herramienta propuesta por [9].

La interpretación de estos niveles en el caso de Aguas y Gaseosas bajo estudio se puede resumir de la siguiente manera: respecto al Procesamiento de datos en la producción, se encuentra en el nivel 4, llamado “Evaluación para planificación de procesos/control” debido a que los datos recabados en la operatoria de producción son nucleados por un sistema para que puedan analizarse de manera conjunta, a fin de mejorar la eficiencia productiva de los planes sugeridos por el área de Planeamiento. En cuanto a la Comunicación M2M, se puede apreciar que se encuentra entre el nivel 3 y 4 (se tomará un valor intermedio de 3,5). Esto se debe a que no todas las partes de la línea de producción tienen acceso a internet, pero se encuentra intercomunicadas entre sí, a fin de lograr un flujo constante de la información sobre la producción. El acceso a internet existe en todas las partes de la línea, la mayoría tiene PC y existe una

red WIFI en la nave. Aunque no todas las máquinas se encuentran conectadas a internet, pero se está trabajando en eso por cuestiones de ciberseguridad.

Las Redes de la empresa y la producción, se puede evaluar con un nivel 2,5, principalmente porque no existe un sistema único de comunicación que sirva sinérgicamente para implementar un proceso productivo y administrativo. Esta dificultad probablemente radique en la utilización de múltiples sistemas para diferentes tareas, complementadas con la utilización del correo electrónico.

Respecto a la infraestructura TIC, se encuentra en un nivel 4 según datos recabados en la entrevista con especialistas del área. Muchos datos son compartidos con un sistema ERP, otros son apreciados solo en cartelería o compartidos en reuniones, lo cual genera un replanteamiento si este nivel estaría correcto o si su madurez en este punto es inferior.

Las Interfaces Hombre-Máquina permiten que en cada proceso se pueda llevar a cabo un monitoreo de la situación de manera descentralizada a través de ordenadores y en algunos casos la utilización de dispositivos Handheld. En primera instancia, se consideró que el valor 4 sería apropiado para este nivel.

Por último, se encuentra le Eficiencia de Pequeños Lotes, ubicándose en el nivel 3 de madurez, debiéndose esto último a la gran capacidad y velocidad de respuesta frente a la necesidad de adaptarse a un cambio repentido de producción. Por ejemplo, cuando se produce un cambio de calibre, sabor o detección de bebida no apta, con necesidad de realizar un rápido descarte/separación para realizar un analizar por el laboratorio.

A modo ilustrativo, y con el fin de observar el potencial en base a la mayor o menor madurez respecto a cada nivel en el ámbito de Producción, se desarrolló un gráfico radial para ver donde se debe apuntar en principio para atender los problemas inmediatos o potencialmente inminentes (ver Fig. 3).

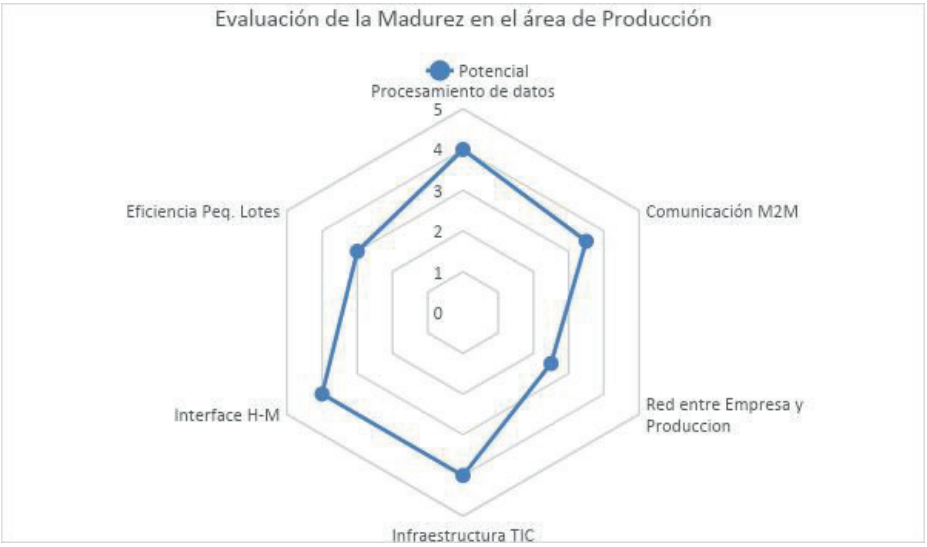

Fig. 3. Gráfico radial que representa la evaluación de madurez y evidencia el potencial según la madurez de la producción, basado en la propuesta de [9]. Fuente: Elaboración propia.

5 Conclusiones

La aplicación del modelo planteado por los autores en este tipo de industrias no es muy conocido, con lo cual, a pesar de que la investigación se encuentra en sus inicios, se avizora la posibilidad de poder recabar información necesaria para lograr un estudio de caso certero que marque un precedente para trabajos similares. Las tecnologías de I4.0 serán fundamentales para que las empresas del rubro consumo masivo, desarrollen ventajas estratégicas respecto a sus competidores. Se está trabajando en el proyecto contemplando no solo los pasos a seguir por el modelo, sino también principalmente atendiendo las necesidades de la compañía bajo estudio. Esto se logrará mediante al acceso a la información como anteriormente se menciona, pero también gracias a la buena predisposición de las distintas áreas de la empresa que se interesan en colorar para que la investigación pueda llevarse a cabo de la mejor manera posible. Esto último permitirá impulsar el potencial de este trabajo como una herramienta eficaz al momento de solucionar problemas con tecnologías 4.0.

La primer fase del trabajo permitió detectar problemas que son considerables desde el punto de vista económico, y que, en economías en retracción como la actual donde los costos son un punto crítico al momento de valuar un resultado, es alentador poder avanzar con una investigación en la cual, aunque sea de modo tentativo, queden planteadas las bases donde se explique cómo una inversión en este tipo de tecnología que permita acercar a la compañía a una Industria 4.0 puede reducir notablemente los costos y mejorar la eficiencia productiva y logística.

La pandemia como oportunidad para reinventarse

Ariel Rodríguez, Yamila Pérez

Francisco Lonas SRL, CEEUIBB; Bahía Blanca, 8000, Argentina

ariel@franciscolonas.com.ar

Breve reseña de la empresa

Francisco Lonas SRL es una empresa bahiense que desde hace 30 años sostiene una constante evolución de calidad y alto compromiso en sus servicios en el mercado de la fabricación de Big Bags, Protección Solar y Lonería Industrial. Fue fundada el 4 de febrero del año 1991 por Ariel Rodríguez, Darío Rodríguez y Francisco Speratti.

Su trayectoria y experiencia le permite brindar un servicio de excelencia, ofreciendo productos de calidad a un precio competitivo junto con un asesoramiento acorde a las distintas necesidades del mercado.

La firma es la primera y única fábrica de Big Bags del sur argentino, con proceso de fabricación bajo norma ISO:9001 de Calidad e ISO:21898 en Labordata (Alemania).

Su principal objetivo es brindar un servicio integral de confianza, garantizando la entrega en tiempo y forma. Brinda una rápida respuesta a sus clientes, poniendo a su disposición una planta fabril de 2500m2.

Problemática detectada

Debido a la caída de las ventas y el desajuste en la cadena de pagos, la firma se vio obligada a tomar las medidas propuestas por el Estado, como créditos a tasa 24%, el programa de asistencia de emergencia al trabajo (ATP), moratoria impositiva al 30/07/2020, etc.

Sin embargo, independientemente de la situación económica complicada que atraviesa como el resto de las empresas en el país, Francisco Lonas SRL asumió importante compromiso a nivel social. Es por esto que, ante la situación de pandemia, decidió realizar un importante aporte en busca de soluciones prácticas e innovadoras en el ámbito de la salud.

Solución implementada

Dadas las maquinarias y el personal capacitado que posee la empresa, junto con el asesoramiento del personal sanitario, se realizaron diferentes elementos para la prevención del contagio del Covid-19:

1. Cortinas divisorias para terapia intensiva e intermedia (Hospital Municipal, Hospital Italiano).
2. Barbijos para fuerzas de seguridad (Policía de la Provincia).
3. Máscaras de protección facial impresas en tecnología 3D.
4. Cabina de traslado para pacientes Covid con una atmósfera controlada de presión negativa y filtros HME en la salida (a pedido de Rotary Club Bahía Blanca).
5. Delantales para personal de salud de los hospitales Municipal de Bahía Blanca, Italiano de Bahía Blanca y Austral de Buenos Aires.

Por otra parte, junto con la comunidad profesional del sistema sanitario de la ciudad, como así también ingenieros y profesores de la UNS, se desarrolló el "CASCO CPAP Bahía Blanca". Es un casco Helmet de VNI (Ventilación No Invasiva) ya existente desde los años '90, para tratamiento de pacientes Covid, con excelentes resultados. Dicho desarrollo fue expuesto en el Consejo Deliberante de la Ciudad, quien presentó el proyecto de declararlo de Interés Municipal, mientras se cumplen todos los pasos de presentación a ANMAT para su aprobación.

Resultados obtenidos:

El desarrollo y la producción de los elementos anteriormente mencionados permitió a la empresa reinventarse y de esta manera mejorar la situación económica y financiera. Además, la participación activa en la lucha contra el COVID 19 generó gran orgullo y reconocimiento en todo el personal. Cabe destacar que los excelentes resultados fueron tanto a nivel local como fuera de la ciudad (Hospital Austral, Hospital Posadas, Hospital Garraham, entre otros).

Comentarios finales

Si bien la situación económica no era la mejor, la empresa pudo reinventarse en una situación de pandemia, y a su vez, de esta manera, hizo un aporte social colaborando activamente contra la lucha del Covid-19. Las capacidades técnicas y creativas de la firma fueron puestas al servicio de nuevos productos necesarios para la situación crítica de salud que atravesó la población. "El mundo que tendremos será el que seamos capaces de lograr "

Abstract

El proceso de Inbound Freight en un proveedor de servicio completo representa un área de oportunidad para reducir costos principalmente por las discrepancias generadas de origen por los proveedores, inducidas por las operaciones del agente aduanal, o producidas durante el transbordo de material en la frontera y el costo de mantener inventario con el agente aduanal. El presente trabajo proporciona la descripción de un proyecto de modelado y simulación para la comparación del proceso actual de Inbound Freight, con un modelo de operación propuesto por el equipo de Comercio de Exterior de Facil NA México, dicha propuesta se desarrolló con la finalidad de los reducir costos relacionados medidos a través de un indicador de desempeño que de manera consistente se reporta por debajo del valor meta, ambos procesos, son modelados e implementados en CPN Tools, los resultados de la simulación permiten la estimación de las discrepancias esperadas en ambos casos, información base que permite la evaluación de sus desempeño para facilitar la toma de decisión de alta dirección de la organización.

Keywords: Medición y mejora de procesos, Simulación basada en eventos discretos, CPN Tools, Dirección de Operaciones, Logística y Transporte

1 Introducción

Diversas investigaciones académicas se centran en los problemas de la cadena de suministro en la industria del automóvil, específicamente en la reducción en el costo logístico, sin embargo, poco se ha discutido sobre la reducción de costos de logística de entrada de la industria automotriz mexicana (Blaga & Jozsef, 2014). La necesidad de desarrollar este proyecto surge a partir de la información y experiencia acumulada en el equipo de gestión de la cadena de suministro, de la empresa Facil NA de México, un proveedor de servicio completo de sujetadores (Compras, Logística, Calidad e Ingeniería). El equipo de gestión de la cadena de suministro ha
tenido la oportunidad de reconocer además de examinar los problemas y dificultades de primera mano considerando el proceso actual, no obstante, no se cuenta con una herramienta que permita el análisis y estimación de los resultados un proceso modificado. Desde el punto de vista estratégico, a partir de la revisión gerencial de los indicadores clave de desempeño (KPIs), se observó que los costos logísticos de la empresa han mantenido la tendencia a superar los valores objetivo, lo que ha influido en el rendimiento operativo, así como en las ganancias de la cadena de suministro. A partir de la medición del Inbound Freight cost (Costo de transporte de entrada) como KPI para los valores simulados de ambos procesos (actual y propuesto), se buscará valorar el impacto esperado del proceso modificado, además se prevé como impacto extendido (inherente a la modificación propuesta) la reducción de tiempos de operación.

2. Diagnóstico y objetivos.

Problema: El Indicador clave de desempeño de transporte de entrada ha estado fuera de objetivo durante doce meses porque ha superado la meta de 4.0% con respecto a las ventas, utilizando a Facil NA de México como caso de estudio.

2.1 Objetivo general.

Desarrollar los modelos de simulación como herramienta para la comparación del desempeño de ambos procesos en términos del KPI seleccionado, para determinar qué proceso es mejor y en qué proporción genera mejores resultados. La propuesta de rediseño será evaluada mediante la implementación de modelos de simulación para

estimar los resultados esperados.

2.2 Objetivos particulares:

- Establecer diferencias de costos de Transporte y Almacenamiento, entre el actual sistema de transporte con trasbordo versus un sistema sin trasbordo.
- Analizar todas las variables operativas actuantes a efectos de plantear modificaciones que posibiliten el cambio del flujo de información permitiendo una mayor visibilidad en la cadena de suministro desde el OEM, retailers hasta los proveedores.
- Ejecutar los análisis de los procesos de acuerdo con el Sistema de mejora continua para el problema de transporte.

2.3 Definición de KPIs y métricas de desempeño

Según el Grupo Aberdeen, el Inbound Freight puede consumir el 40% del gasto promedio una organización de flete anual o 3.6% a 5.2% de las ventas anuales totales de una empresa. El KPI para este caso de estudio es *Inbound Freight* que lo podemos definir como el costo del abastecimiento, agilización y recepción de bienes, que está llegando a la organización.

Operacionalmente, el KPI *Inbound Freight* es calculado como el porcentaje de los gastos totales del transporte de entrada entre las ventas mensuales. En ambos casos (operación actual y propuesta) aplica a todo el gasto facturado y el objetivo es de 4.0% mensual, como referencia del desempeño en esta métrica, en la tabla 1 se observa los resultados del año 2019, como puede verificarse con estos datos, sólo en 3 meses de los doce, se registraron valores dentro del objetivo o por debajo (lo que implica una operación más eficiente aún), pero 75 % de las veces el desempeño supero el valor máximo establecido como objetivo. El sistema de calidad de la compañía indica que si el indicador no es alcanzado debe realizarse una acción correctiva, pero al momento las actividades desarrolladas no han sido efectivas por lo que se desarrolló una propuesta de proceso modificado con el cuál se busca la reducción de costos en el transporte de entrada, de tal forma que se definió como necesario la aplicación de herramientas de modelado y simulación para verificar el impacto esperado de las acciones definidas.

Tabla 1. Resultados del KPI Inbound Freight del año 2019

Mes	**Inbound Freight**		**Mes**	**Inbound Freight**	
	Real (%)	**Meta (%)**		**Real (%)**	**Meta (%)**
Enero	**4.00**	4.00	**Julio**	**3.30**	4.00
Febrero	4.50	4.00	Agosto	4.30	4.00
Marzo	5.20	4.00	Septiembre	4.20	4.00
Abril	5.10	4.00	Octubre	4.60	4.00
Mayo	4.70	4.00	Noviembre	4.70	4.00
Junio	**3.80**	4.00	Diciembre	4.90	4.00

3. Análisis del proceso y desarrollo de propuesta

o rediseño del proceso 3.1 Situación actual

- Los 4 proveedores más grandes pueden pasar por un proceso logístico diferente al de los suministros más cortos, ver figura 1.

- Las discrepancias son evaluadas por nuestro equipo en WH Toluca / Saltillo, aunque el agente aduanal realizo la misma actividad en días anteriores

- Alto costo: retención, revisión, informe por aduanas, proveedor de transporte. • • • La logística (de EE. UU. A MX) es administrada por el equipo en las oficinas centrales de Norteamérica en Ohio Estados Unidos, pero no tenemos suficiente soporte para resolver problemas.

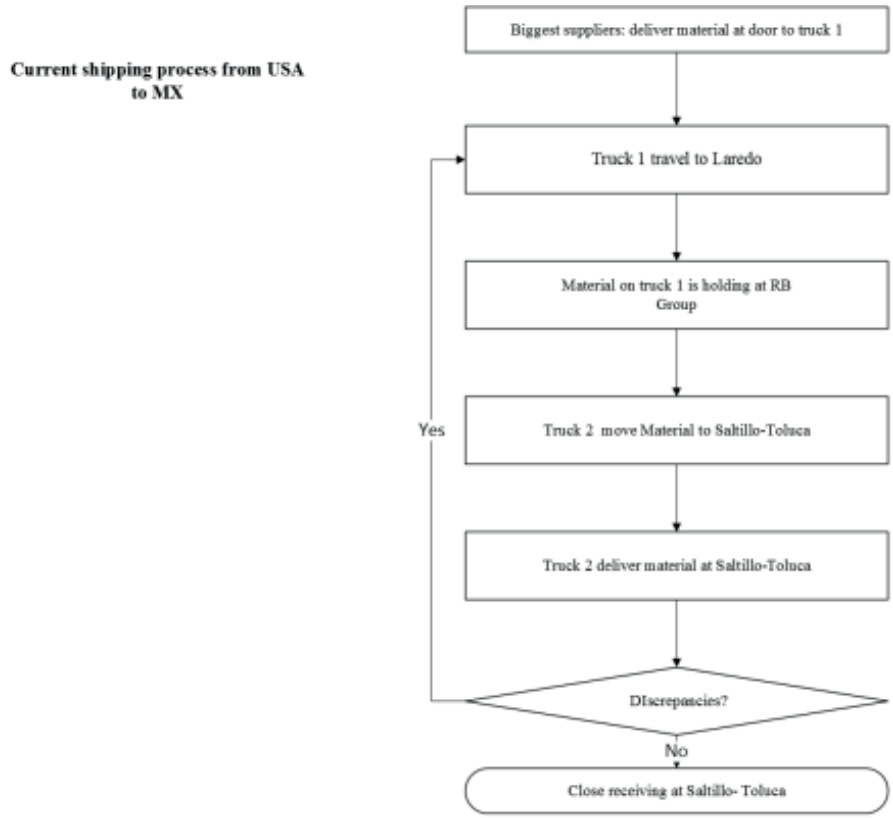

Fig. 1. Diagrama de flujo Proceso actual de logística de entrada

3.2 Situación propuesta

El equipo de comercio exterior de la región Norte América del FSP (full service provider) donde se realiza la propuesta de Re diseñar e integrar la cadena de suministro en el proceso de logística de entrada al identificar que en el proceso de Inbound Freight del año 2019 el costo fue 4.48% el de las ventas anuales de los datos mostrados en la tabla 1, el KPI logística de entrada estuvo 0.48% fuera de objetivo, se detectó el costo de la actividad del agente aduanal actual para los cuatro mayores proveedores de manufactura de la cadena de suministro representaba el 0.53% de las ventas anuales. Después mediante una lluvia de ideas del equipo de comercio exterior detectaron que el proceso de inspección de material en facturas, cantidad y etiqueta se repetía en el agente aduanal y posteriormente en los almacenes de Saltillo y Toluca. De acuerdo con lo anterior, se definieron las siguientes acciones:

• Realizar el proceso sin la inspección del material (factura, cantidad y etiqueta) en el almacén del agente aduanal.

• Analizar el lead time de los cuatro proveedores sin la operación anterior

• Comparar los costos por discrepancias del proceso actual contra

el proceso propuesto. • Evaluar el KPI de Inbound Freight.

• Documentar el proceso de mejora de continua.

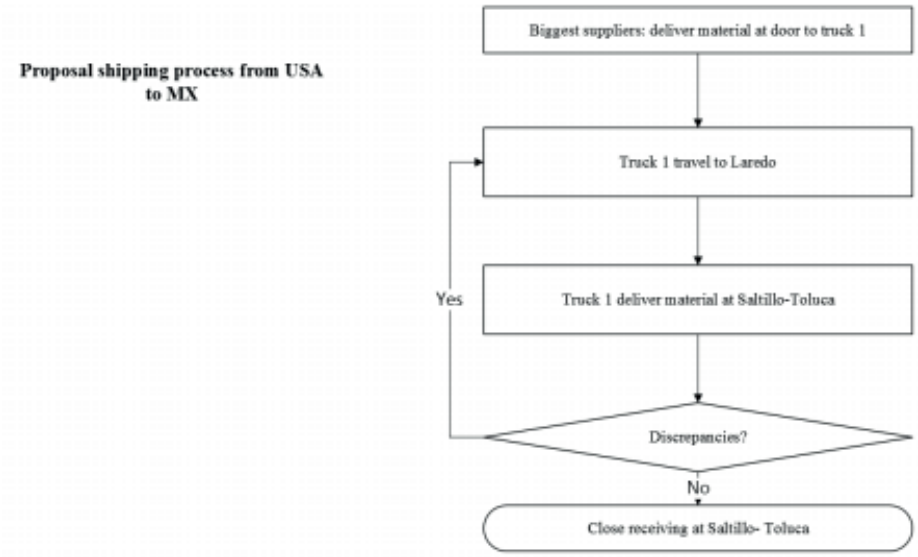

Fig. 2. Proceso propuesto de logística de entrada

4. Simulación como método de estimación de los resultados esperados

El presente proyecto, toma como referencia el trabajo de (Wang & Chen, 2016), donde se combina el sistema logístico real de un fabricante automotriz, utilizando el modelo de red Petri y el software de simulación CPN Tools para simular y proponer un método de optimización efectivo basado en los resultados de la simulación. La simulación como tal es un proceso y en general consta de las siguientes etapas:

- Definición del sistema: Para tener una definición exacta del sistema que se desea simular, es necesario hacer primeramente un análisis preliminar de éste, con el fin de determinar la interacción con otros sistemas, las restricciones del sistema, las variables que interactúan dentro del sistema y sus interrelaciones, las medidas de efectividad que se van a utilizar para definir y estudiar el sistema y los resultados que se esperan obtener del estudio.
- Formulación del modelo: En la formulación del modelo es necesario definir todas las variables que forman parte de él, sus relaciones lógicas y los diagramas de flujo que describan en forma completa el modelo.
- Colección de datos: Es importante que se definan con claridad y exactitud los datos que el modelo va a requerir para producir los resultados deseados.
- Implementación del modelo en la computadora: Con el modelo definido, el siguiente paso es decidir si se utiliza algún lenguaje para procesarlo en la computadora y obtener los resultados deseados. • Validación: A través de esta etapa es posible detallar deficiencias en la formulación del modelo o en los datos alimentados al modelo.
- Experimentación: La experimentación con el modelo se realiza después que éste haya sido validado. La experimentación consiste en generar los datos deseados y en realizar un análisis de sensibilidad de los índices requeridos.
- Interpretación: En esta etapa del estudio, se interpretan los resultados que arroja la simulación y con base a esto se toma una decisión.
- Documentación: Dos tipos de documentación son requeridos para hacer un mejor uso del modelo de simulación. La primera se refiere a la documentación del tipo técnico y la segunda se refiere al manual del usuario, con el cual se facilita la interacción y el uso del modelo desarrollado.

5. Modelado y simulación

5.1 Descripción proceso actual

Para el desarrollo de los modelos, se emplean las Redes de Petri Coloreadas (RPC's), formalismo para la simulación basada en eventos discretos aplicable a sistemas de manufactura y logísticos (Piera, 2004).

A continuación, se describe el modelo del proceso actual, implementado en CPN Tools (Figura 3). El total de órdenes a simular, provenientes de los cuatro proveedores, se hallan contenidas en un nodo lugar del tipo "source" denominado "Ordenes totales", la información sobre la distribución de las órdenes por cada proveedor A, B, C y D, quienes envían determinadas ordenes de acuerdo al ERP existente en la cadena de suministro en un FTL (Full Truck Load) hacia la frontera en Laredo, Texas USA donde se realiza un proceso de cruce de frontera de USA a México, se indican en el modelo a través de los valores en los nodos lugar "DistProveedores Saltillo" y "DistProveedores Toluca", información obtenida a partir del análisis de los datos históricos, para ambos nodos lugar se mantiene la siguiente equivalencia de los valores A= 1, B= 2, C=3 y D=4, para identificar a cada uno de los proveedores, y la variable que se emplea es P.

La información referente a la distribución desde cada proveedor hacia cada destino (Saltillo o Toluca), es de manera similar obtenida mediante la revisión de los valores registrados en el año anterior, dicha información se suministra en el nodo lugar "DistDestinos", en este caso Saltillo se denota con el número 1 y Toluca con el número 2, en tanto la variable empleada es la letra D.

Las transiciones (rectángulos) corresponden a la acción o evento de similar una orden con su correspondiente origen y destino, es decir la asignación de los valores de P y D, cada una de las órdenes procesadas se registra en el nodo lugar "OrdenesDespachadas", dicha información se suministra para la siguiente operación, denominada "Inspección AA", la información histórica de las discrepancias de origen atribuibles a los proveedores se introducen en el nodo lugar "Discrepancias Proveedores", en donde para cada proveedor se tiene la probabilidad de generar discrepancias, dicha información de tiene clasificada para cada combinación (P,D), la variable que simula la existencia o no de una discrepancia es el dígito que se asigna a la letra Q, variable binaria con 0 para el caso de no existir discrepancia y 1 para el caso de existir discrepancia.

En función del destino de cada orden, el flujo se distribuye hacia el nodo lugar "Entrada Cedis Saltillo" si D=1, y hacia "Entrada Cedis Toluca", en el caso D=2. En ambos nodos se almacenan las órdenes procesadas hasta ese punto, las cuáles serán introducidas en la operación de inspección por la empresa en cada uno de los Centros de Distribución (Cedis), cada inspección está indicada como una transición

independiente, dicha operación se simula con la información correspondiente al desempeño histórico observado para el agente aduanal (AA) respecto a las discrepancias inducidas en cada orden, información contenida en el nodo lugar "DistDiscrepancias AA", que de manera análoga a las discrepancias de origen, se tiene clasificada para cada origen, el valor que se asigna para las discrepancias inducidas es indicado por la variable I, que adopta de manera análoga valores 0 y 1, tal como se definió para los valores de Q.

Finalmente, las órdenes libres de discrepancias (con Q=I=0) se depositan en el nodo lugar "Ordenes OK Saltillo" y "Ordenes OK Toluca", según corresponda, complementariamente las órdenes que durante la simulación, recibieron valores 1 en las variables Q o I, son depositadas en los nodos lugar "Ordenes Discrep Saltillo" y "Ordenes Discrep Toluca" Todas las ordenes ok forman parte del inventario disponible y visible para venta en la cadena de suministro por otra parte las ordenes con discrepancias representan inventario que no será visible para venta para la cadena de suministro. En el caso del proceso modificado (Figura 4), el modelado es equivalente, con la evidente diferencia de que se ha suprimido la "Inspección AA", por lo que ahora después de la simulación de la distribución de las órdenes (asignación de valores de P y D, se realiza operación de inspección en los Cedis y se clasifican las órdenes de acuerdo con el atributo de calidad Q exclusivamente.

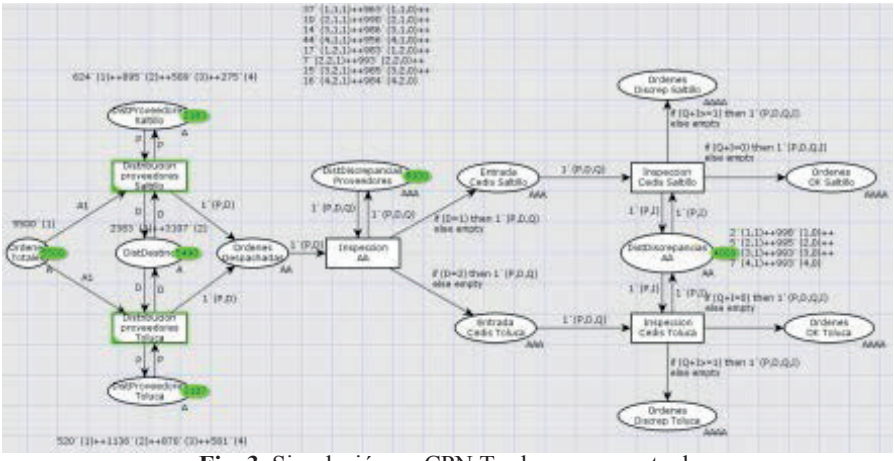

Fig. 3. Simulación en CPN Tools proceso actual

Fig. 4. Simulación en CPN Tools proceso propuesto

6. Resultados

Con el objetivo de obtener datos estadísticos para facilitar la toma de decisión de la alta dirección de Facil NA de México, se realizaron 30 experimentos de ambos procesos, simulando en cada experimento un total de 5500 órdenes, volumen equivalente a un año de operación. En la figura 5 aparecen los resultados simulados para el proceso actual de logística de entrada donde el material es inspeccionado por el agente aduanal lo cual genera discrepancias adicionales a las del proveedor.

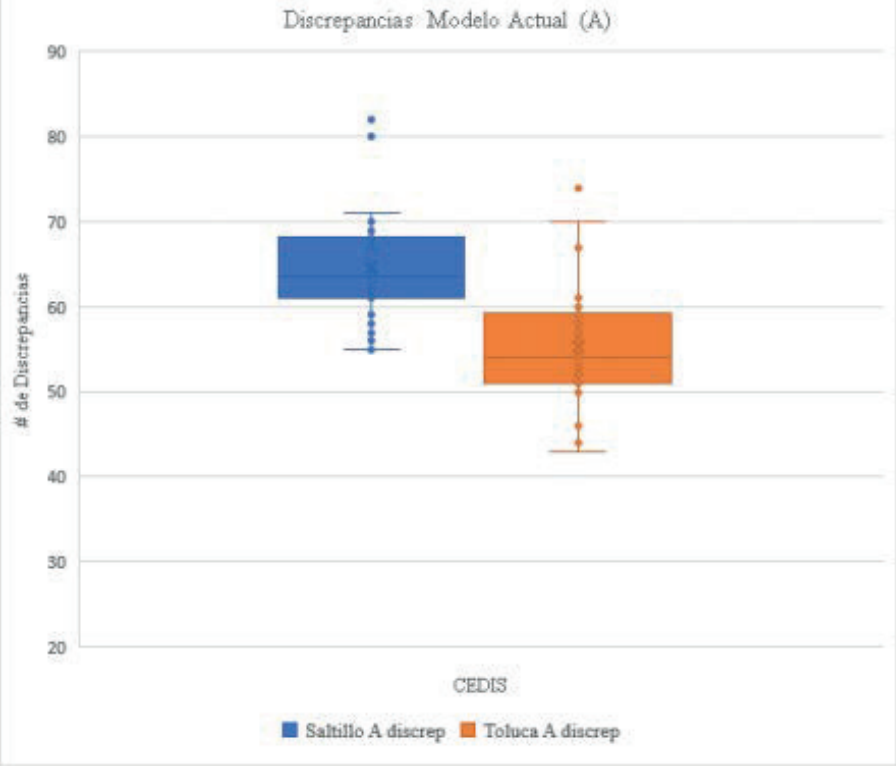

Fig. 5. Número de discrepancias actuales en la sucursal de Saltillo y Toluca.

Como se puede observar en la sucursal de Toluca, considerando el proceso actual, recibe una media de 53 órdenes con discrepancias y la sucursal de Saltillo se recibe una media de 63, a partir de revisar el rango de valores obtenidos, observamos que los valores están entre 43 y 74 casos anuales para el caso de Toluca, en tanto Saltillo reciben entre 55 y 82 órdenes con discrepancias.

De manera análoga, para la simulación de los valores empleado el proceso modificado, se registran los valores obtenidos para los 30 experimentos, en la figura 5 los datos muestran que el modelo modificado propuesto, representa una reducción en los valores del número de órdenes con discrepancias, 59 casos en el escenario máximo para ambas sucursales y en el caso mínimo en 30 para Saltillo y 32 para Toluca. Si hacemos una comparación de los valores medios, también muestran una reducción, 47 órdenes para el sitio del norte de país y 42 órdenes para el centro de distribución del segundo sitio. Otro aspecto mostrado en la figura 3 es el cambio a un proceso lean donde se eliminarían operaciones que no agregan valor porque generan costos de tiempo de

inspección, movimiento de material, transporte y costos de mantener inventario en las instalaciones del agente aduanal.

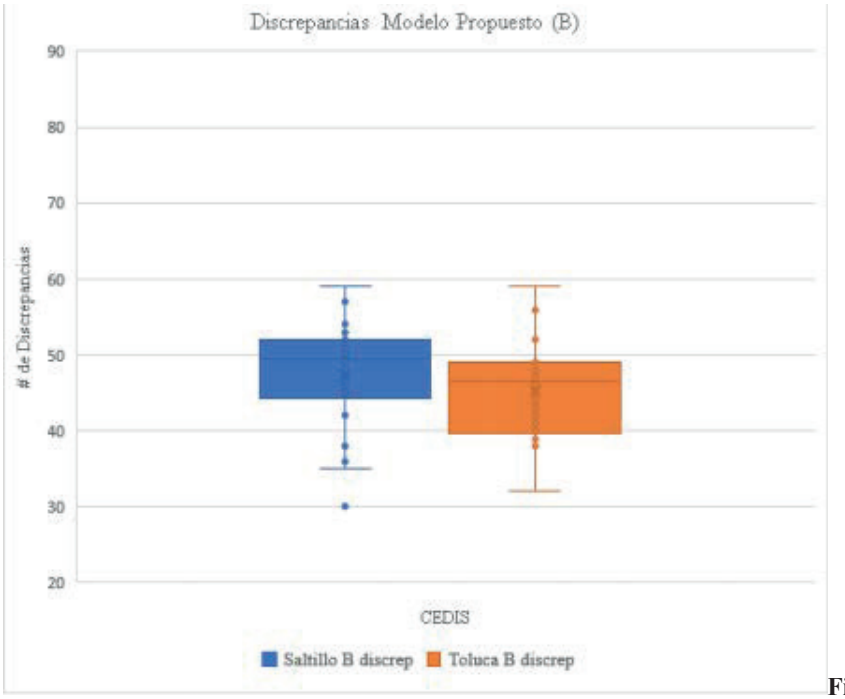

Fig. 6. Número de discrepancias simuladas en la sucursal de Saltillo y Toluca.

7. Conclusiones

El presente documento ofrece datos estadísticos para la toma de decisión del cambio de proceso de Inbound Freight en la empresa Facil NA de México, indicador que esta fuera de objetivo por el costo de esta operación. Los resultados de los 30 experimentos muestran una reducción de órdenes con discrepancias anuales promedio de 65 a 47 casos para la sucursal de Saltillo y de 55 a 42 para Toluca, valores que representan una potencial reducción de 37% y 23 % respectivamente.

La implementación del modelo propuesto implica una reducción directa de costos porque el agente aduanal cobra por cada factura inspeccionada, físicamente (pallet/caja) y administrativamente (errores de cantidad, numero de parte etc. en etiqueta o factura), esta inspección estaría eliminada en el proceso propuesto, así como el mantener el inventario en las instalaciones del proveedor mencionado.

Sin embargo, tal como se evidencia mediante la simulación de desempeño de cada proceso evaluado, la implementación del modelo modificado representa la generación consistente de ahorros operativos y financieros, con la reducción órdenes con discrepancias inducidas por una operación prescindible que no agrega valor y que si agrega tiempos de procesamiento y mermas por errores y fallas en la manipulación de las órdenes por parte del agente aduanal. Complementariamente, existe un beneficio en términos del incremento de la confiabilidad y consistencia de los procesos de abastecimiento (efectividad de las órdenes solicitadas y las realmente disponibles en inventario para la venta), que de manera directa incrementa la capacidad de la empresa para brindar un nivel de servicio competitivo.

Métodos y modelos de investigación

La Manufactura Aditiva como herramienta clave en la modernización de los procesos de fundición

Prof. Ing. Danilo I. Pizzolitto

DP3D Ingeniería, Rosario, 2000, Argentina

danilop@dp3dingenieria.com.ar

Resumen. En el presente trabajo abordaremos una de las tantas posibilidades de la impresión 3D en el campo industrial: la fabricación de modelos patrón para procesos de fundición. Comenzaremos con una breve reseña de los métodos de manufactura clásicos, para pasar a la manufactura aditiva, sus ventajas y desventajas. Luego estudiaremos el procedimiento necesario para la obtención de los modelos, materiales seleccionados, y factores a tener en cuenta. Finalizamos con algunos datos interesantes que se fueron obteniendo con la aplicación de esta técnica y concluimos sobre la aplicabilidad de la misma.

Palabras clave: ingeniería mecánica, manufactura aditiva, impresión 3d, fundición, industria 4.0, procesos industriales.

1 Introducción

Históricamente han existido tres grandes familias de métodos de manufactura bien definidos. Los mismos son: la manufactura extractiva, la manufactura por fundición y la manufactura por conformado. En la década de 1980 surgen las primeras patentes de lo que será la técnica de fabricación moderna, una cuarta que se suma a las anteriores: la manufactura aditiva.

Veremos una breve reseña de las mismas.

1.1 Manufactura Extractiva

Consiste en la remoción sucesiva y controlada de material, partiendo de una materia prima base, hasta obtener la pieza deseada. Ejemplos de este tipo de manufactura son los procesos de mecanizado CNC en los cuales se parte de un “bloque” metálico con sobre material y se lo trabaja por arranque de viruta hasta obtener la pieza deseada.

2

Fig. 1. Proceso de mecanizado CNC, técnica de manufactura extractiva.

1.2 Manufactura por Fundición

Consiste en calentar nuestra materia prima hasta fundirla, para luego verter dicho fundente en un molde. Al enfriarse y solidificar, obtendremos nuestra pieza con la geometría del molde en el cual hemos vertido nuestra materia prima.

Este método de manufactura se corresponde a infinidad de piezas de ingeniería en las cuales nuestro fundente es metálico, por ejemplo, aceros o aleaciones de aluminio.

Fig. 2. Proceso de fundición en acero.

1.3 Manufactura por Conformado

La manufactura por conformado consiste en aplicar un esfuerzo mecánico a nuestra pieza para deformarla (conformarla) hasta la geometría deseada, sin aplicación de calor (al menos no hasta el estado líquido de la materia prima). En sí, son procesos basados en la deformación plástica de los materiales. Como ejemplo podemos

mencionar procesos industriales como el estampado de chapas en los cuales, con ayuda de una matriz y una prensa hidráulica, una placa plana de metal adquiere otra forma compleja por aplicación de una gran fuerza mecánica.

Fig. 3. Matriz para estampado de chapas.

Es momento ahora de introducir una cuarta técnica de manufactura, de surgimiento mucho más reciente que las tres anteriores. La misma se conoce como **Manufactura Aditiva**.

1.4 Manufactura Aditiva:

Es una familia de técnicas de fabricación que consisten en la creación de objetos mediante la adición progresiva de material. Por la esencia del método productivo, la manufactura aditiva es un proceso en el cual se minimizan los desperdicios, y mediante el cual se pueden obtener diversas geometrías difícilmente alcanzables mediante métodos de manufactura tradicionales. Su contraparte es la manufactura extractiva. Resulta interesante destacar que estos procesos de manufactura son altamente automatizados, por lo cual suelen no requerir supervisión.

4

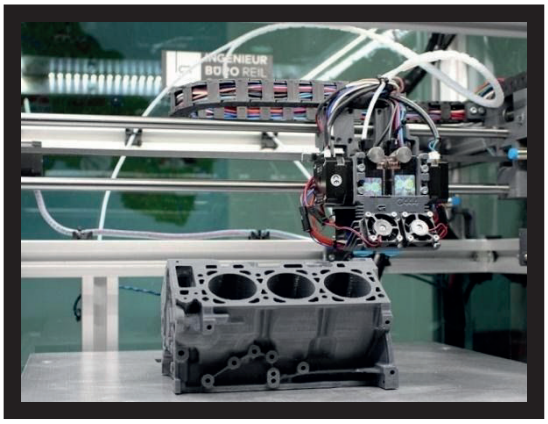

Fig. 4. Impresora 3D, manufactura aditiva.

Como bien se puede concluir del apartado anterior, la impresión 3D es un método de manufactura aditiva que consiste en la deposición controlada de material, hasta obtener cierta geometría deseada.

Si bien existen varias técnicas diferentes de impresión 3D, algo en común en todas ellas es que la creación de objetos se da por la aplicación de sucesivas capas, una tras otra, las cuales hacen que el objeto impreso vaya "creciendo" según cierta orientación. En la presente publicación, haremos referencia exclusivamente a la tecnología FDM, es decir, aquella que se basa en la deposición de polímeros fundidos para obtener piezas.

2 Desarrollo

Como estudio de ingeniería especializado en técnicas de Manufactura Aditiva, una de nuestras principales metas es resolver problemáticas de la industria mediante la aplicación de la Impresión 3D y tecnologías afines. Analizando las necesidades de una empresa a la cual se le brindan servicios, se descubre el enorme cuello de botella que generaba la fabricación de modelos para fundición mediante técnicas tradicionales de tallado manual y mecanizado en madera o aluminio.

Ampliaremos ahora sobre el concepto de Manufactura por Fundición, abordado en la Introducción, para ahondar un poco en los detalles de cómo es el proceso aplicado. Como mencionamos, el hecho de tomar una materia prima, fundirla, y verterla en un molde, es lo que comúnmente llamamos fundición. Si la materia prima es metálica, el método más tradicional consiste en utilizar moldes de arena, en los cuales se genera una impronta con la forma del objeto a replicar y donde se verterá el fundente.

Los metales fundidos no pueden difundir a través de los límites de la arena compactada, por lo cual quedarán "estancados" en esas aberturas hasta el momento en el que solidifiquen y puedan ser retirados.

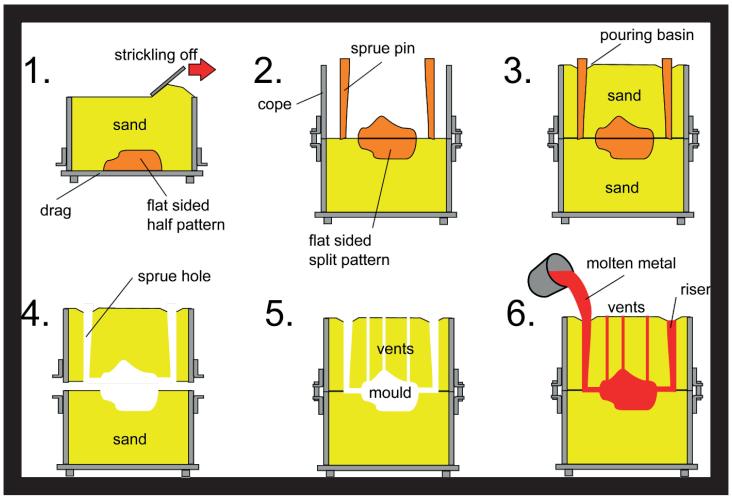

Fig. 5. Proceso de moldeo en arena.

La impronta en la arena se genera a partir de un objeto conocido como modelo, el cual tiene la forma y dimensiones tales que permite la obtención del objeto a fabricar teniendo en cuenta la contracción del material a fundir, sobre materiales para posterior mecanizado, etc. Es decir, cada modelo de fundición debe ser calculado, diseñado y construido de forma anterior al proceso de fundición. Los materiales más utilizados para fabricar estos modelos, son el aluminio y la madera. El primero se suele trabajar con mecanizado CNC, y el segundo se suele utilizar una mezcla entre mecanizado CNC, mecanizado manual y tallado manual, haciendo que sea un trabajo muy laborioso y artesanal. Aquí es donde entra en juego la impresión 3D.

La impresión FDM se basa en 3 elementos principales: una plataforma de impresión en la que se imprime la pieza, una bobina de filamento que sirve como material de impresión y un cabezal de extrusión a través del cual fluye el filamento. En resumen, el filamento es succionado y fundido por el extrusor de la impresora 3D, que deposita el material de forma precisa capa por capa sobre la plataforma. Una vez que la plataforma calefaccionada y el pico del extrusor llegan a las temperaturas configuradas, comienza a extruírse un filamento de material sobre la plataforma a través de una boquilla que se mueve sobre 3 ejes (x, y, z) comandada por un código-G generado previamente en un software de impresión 3D. Al finalizar cada capa, la plataforma se separa del extrusor y comienza la impresión de la siguiente.

Existen diversos materiales para impresión FDM, y tras un análisis técnico se llegó a la conclusión de que, por las cualidades mecánicas, térmicas, y la precisión dimensional, el polímero conocido como PET-G es el ideal para resistir las solicitaciones de los modelos de fundición: Las presiones de la compactación de la arena, y condiciones térmicas levemente adversas por el ambiente en el que se utilizarán.

La implementación de Impresión 3D para la fabricación de estos modelos significó agregar algunas etapas al diseño constructivo de la pieza. Los modelos que antes se construían en una sola pieza, por una limitación tecnológica debían ahora ser

construidos en varios, para luego ser armados, sellados y soldados. Aun así, las ventajas fueron notables desde un primer momento.

Veamos un resumen de las etapas de diseño y fabricación de los modelos de fundición.

1. Análisis de la pieza a fabricar. Todo proceso de construcción de un modelo de fundición, parte del plano de definición de la pieza metálica que deseamos obtener, independientemente del tipo de proceso que se requiera para ello. Aquí debemos tener en cuenta ciertos factores, si existen caras de contacto con otras partes, tratamientos térmicos, o tratamientos de recubrimiento superficial para evaluar las regiones que deberán tener sobre material para posterior mecanizado. Los procesos de fundición raramente se utilizan como método único para fabricar una pieza, sino que son acompañados de otros métodos de manufactura.
2. Diseño del modelo. Basándonos en todo lo analizado en el punto anterior, se ejecuta el diseño del modelo considerando contracciones, ángulos de desmolde, sobre materiales, etc.
3. Modelado 3D del patrón. Utilizando software de diseño asistido por computadora (CAD) generaremos la representación digital del modelo de fundición.
4. Adaptación del modelo para impresión 3D. Aquí partimos del modelo ideal, para dividirlo en las piezas necesarias según la geometría óptima para imprimir, tamaño del volumen de impresión con el que contamos, etc. Además, se incorporan alojamientos y pines de unión para el posterior pegado de las piezas.
5. Laminación. Esta etapa, también conocida como *slicing*, consiste en procesar los modelos 3D obtenidos en la etapa anterior por medio de un software de Impresión 3D, en el cual incorporaremos todos los parámetros que darán las características al modelo físico que obtendremos. Esta es una de las etapas más críticas del proceso.
6. Impresión 3D. En la etapa anterior obtenemos un archivo conocido como *gcode*, el cual contiene las instrucciones codificadas que interpretará la impresora para materializar nuestros diseños. Este proceso puede tardar más de 80 horas, según la complejidad y tamaño de la pieza. Si bien las impresoras 3D son equipos autónomos, la etapa de impresión requiere supervisión constante para detectar fallas, errores y evitar el desperdicio de material en caso de que no se esté ejecutando de forma correcta.
7. Post procesado. Se procede al pegado, ensamblado de los modelos, soldadura de los mismos y rectificado superficial de las zonas de unión entre partes.
8. Verificación. Es importante hacer una verificación dimensional y geométrica de los modelos para asegurarnos de que estén dentro de las tolerancias esperadas y puedan ser utilizados.

A partir de aquí, el proceso de fundición es el mismo que se utiliza desde hace siglos, sin variantes en los equipamientos, los insumos ni las condiciones de trabajo.

3 Conclusión

La implementación de modelos impresos en 3D en los procesos de fundición en arena significaron una disminución de tiempos aproximada del 67%, y una disminución de

costos que ronda el 80% en la fabricación de dichos modelos patrón. Además, se obtienen piezas más livianas que pueden ser operadas por una sola persona, a diferencia de un patrón similar fabricado por ejemplo en aluminio macizo mecanizado.

Respecto a la durabilidad, al día de hoy los patrones fabricados no tienen signos de desgaste luego de 6 procesos de compactación y colada. Se estimó una vida útil de 20 procesos.

Es evidente que la gran ventaja de estos modelos de fundición está en aplicaciones de baja escala de producción. Modelos de aluminio o madera tienen una vida útil estimada de 30 años de trabajo continuo, por lo cual pueden resultar económicamente convenientes frente a la impresión 3D. Sin embargo, dicha inversión inicial es unas 5 veces más elevada lo cual quita flexibilidad a la hora de plantear mejoras en el modelo para mejorar las características físicas, dimensionales y/o de terminación de las piezas a fundir.

Optimización de tiempos en Ordenes de Transporte en empresa de servicios petroleros

Marcelo Fabián Chaulet

Halliburton Argentina, Bahía Blanca, 8000, Argentina

marcelofabian.chaulet@halliburton.com

Resumen

La mejora continua dentro de las organizaciones es fundamental para la eficiencia y calidad de los procesos. El contexto actual ha puesto sobre la mesa enormes desafíos, sobre todo en el plano tecnológico, donde las comunicaciones eficientes entre los empleados son clave a la hora de mejorar la productividad en las empresas. Re-pensar cómo se trabaja y se procesa la información ha conducido a adquirir cierta elasticidad en los agentes que intervienen en todos los niveles organizacionales con el fin de seguir siendo competitivos dentro de un mercado global muy dinámico. En el presente artículo se aborda la incorporación de una mejora relacionada con el manejo de documentación y los resultados obtenidos. Este proceso corresponde al área de Materiales de la empresa Halliburton Argentina, en colaboración con su proveedor directo, Sea White S.A. La acción de mejora se centró en la gestión de las órdenes de transporte con el fin de optimizar los tiempos en cada una de las etapas que requieren las mismas desde el origen hasta su procesamiento definitivo. Cada eslabón que compone el proceso es vital para alcanzar la excelencia operativa. A través de este trabajo se intenta mostrar como pequeños cambios en el flujo de la documentación producen mejoras significativas en el procesamiento de órdenes de transporte.

Palabras clave: Mejora Continua, optimización, órdenes de transporte.

1. Introducción

El proceso de mejora continua, incorporado por toda una empresa, implica un flujo continuo de innovación [1]. Encuentra aplicación en diversas áreas.

Uno de los conceptos más utilizados e implementados en la industria es el Ciclo de Deming [2] (Fig. 1) conocido como PDCA (Del inglés, Plan-Do-Check-Act) o PHVA (Planificar-Hacer-Verificar-Actuar). Este ciclo es una estrategia basada en la mejora continua de la calidad en cuatro pasos.

- Planificar: Se detecta una oportunidad y se establecen las actividades del proceso, necesarias para obtener el resultado esperado.

- Hacer: Se realizan los cambios para implantar la mejora propuesta. Generalmente conviene hacer una prueba piloto antes de realizar los cambios a gran escala.
- Verificar: Se monitorea la implementación y se evalúa el plan de ejecución, documentando las conclusiones (resultados y aprendizajes).
- Actuar: A partir de los resultados conseguidos en la fase anterior, se procede a recopilar lo aprendido y a ponerlo en marcha. También suelen aparecer recomendaciones y observaciones que suelen servir para volver al paso inicial de Planificar y así el círculo nunca dejará de fluir.

Figura 1. Ciclo de Deming

El presente artículo se focalizará en la aplicación de una mejora en una empresa de servicios petroleros, con el fin de lograr una optimización en tiempos de un proceso. Esto está estrechamente relacionado con el concepto japonés Kaizen (kai, que significa "cambio" y "zen", que significa "bueno" o "beneficioso"). Kaizen simboliza mejora continua en la vida personal, en el hogar, en lo social y en el trabajo, basado en acciones concretas, simples y poco costosas, que atraviesan a la organización en todos los niveles, desde los gerentes hasta los operarios. [3]

El contexto actual y la escasez de personal presencial, el home office y las prácticas asociadas llevaron a planificar de otro modo el flujo de la información y las formas de comunicación dentro de las compañías.

2. Descripción del sistema bajo estudio

2.1 Halliburton Argentina

Halliburton Argentina posee en Bahía Blanca, Buenos Aires, una planta de procesamiento de minerales situada en el área de acceso al puerto de la ciudad. En la Fig. 2 se observa el predio de la planta y los diferentes sectores dentro del área ejecutiva. La misma posee dos molinos que procesan un mineral, la Baritina, obteniendo dos productos finales: Barita a granel y en bolsones. La compañía trabaja

en las instalaciones de la empresa Sea White S.A. (SW), la cual es la principal proveedora de servicios para que Halliburton desarrolle su labor.

Dentro de la organización, se encuentra el área de Materiales, cuya función radica en la óptima gestión de inventario en almacén y su flujo desde que se procesa la materia prima hasta que el producto terminado llega a las manos del cliente. Para registrar estos movimientos de materiales, la empresa utiliza la tecnología SAP como ERP (Enterprise Resource Planning, por sus siglas en inglés). Se calcula que entre el 70% y el 80% del mercado de grandes empresas utilizan sus productos. [4]

Figura 2. Localización de sectores dentro de la Planta Sea White – Halliburton

2.2. Operación de la Planta

El proceso inicia cuando la materia prima (Piedra de Baritina) ingresa a premolienda, para aquellas piedras que requieran reducir su tamaño para utilizarse en los equipos posteriores. Una vez consumida esta etapa, el producto se dirige al sector de Molienda, donde se encuentra dos molinos, operados por personal de Sea White. El producto final, con las condiciones de humedad y densidad adecuados, se almacenan a granel en un Silo y en bolsones en depósito. A partir de la fabricación de estos productos finales, se generan las denominadas Ordenes de Producción (OP). Estas últimas son ingresadas a SAP por Halliburton por medio de diferentes operaciones llamadas Transaction Code (T-CODE).

Estos materiales producidos tienen una demanda real y son solicitados por clientes internos y externos. Los clientes internos son las demás bases que posee Halliburton a lo largo del país (Neuquén – Buenos Aires – Comodoro Rivadavia y Mendoza, entre sus principales) y los clientes externos son las operadoras que requieren el material directo en pozo o en sus almacenes intermedios. Cuando el material se envía directo

al cliente, se genera una Orden de Venta (SO - Sales Order, por sus siglas en inglés) En cambio, cuando el destino final es un cliente interno, se requiere una Orden de Transporte (TO – Transport Order, por sus siglas en inglés) y en la cual nos vamos a centrar en el presente trabajo.

2.3. Procesamiento de una Orden de Transporte

Una Orden de Transporte o Transport Order (TO) es una transacción utilizada en SAP para reflejar movimientos de materiales entre las locaciones que posee Halliburton a nivel país. La generación de esta nace cuando el cliente interno solicita una determinada cantidad de material para una locación en particular. El equipo de Planificación de la Demanda (DP - Demand Planning, por sus siglas en inglés) es el responsable de generarla y debe detallar el origen, el destino, el número que identifica al material, las cantidades requeridas, el costo del flete, entre otros. Al completar esta información, SAP crea un número de TO para este movimiento.

El proceso de generación de TO para Tolvas de Barita a Granel se compone de las siguientes etapas (Fig. 3):

1) El área de Materiales de Halliburton solicita a DP la creación de una TO. Se deben detallar la planta origen, la planta destino, el número de material y la cantidad requerida. Generalmente se solicita por un período de siete (7) días para evitar solicitar TOs de manera reiterada.

2) La barita se carga en camiones tolva a través de un silo. Por cada unidad, el área de Molienda de SW emite la documentación necesaria para procesar el viaje. El documento más importante es el Remito, donde se detalla el número de TO correspondiente al viaje.

3) Los remitos, una vez elaborados, se envían al área de Balanza.Esto implica el traslado de estos desde las instalaciones de la molienda. Finalmente, son cargados al sistema de SWpor personal del área de Balanza.

4) El área de Materiales de Halliburton descarga los remitos desde el sistema donde fueron cargados.

5) Terminada la semana, se procesa la TO, es decir, se ejecuta el despacho SAP. Se envía un e-mail con las personas implicadas y se adjuntan los remitos asociados a la TO semanal. Asimismo, se brinda un detalle en una tabla de Excel para tener trazabilidad.

Este proceso descripto presenta falencias identificadas tanto desde el equipo de Halliburton como el de Sea White. Ante esta situación, se determina en conjunto, idear alguna alternativa para mejorar el proceso.

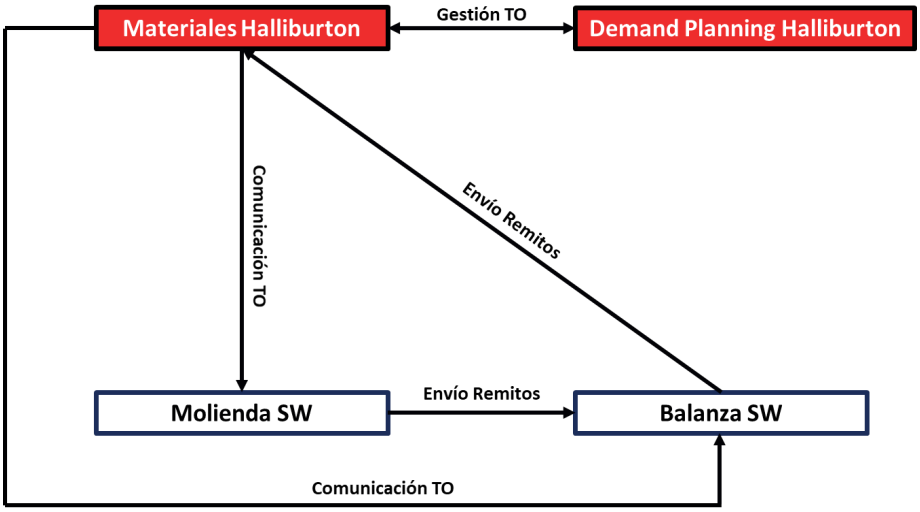

Figura 3. Flujo de documentación original

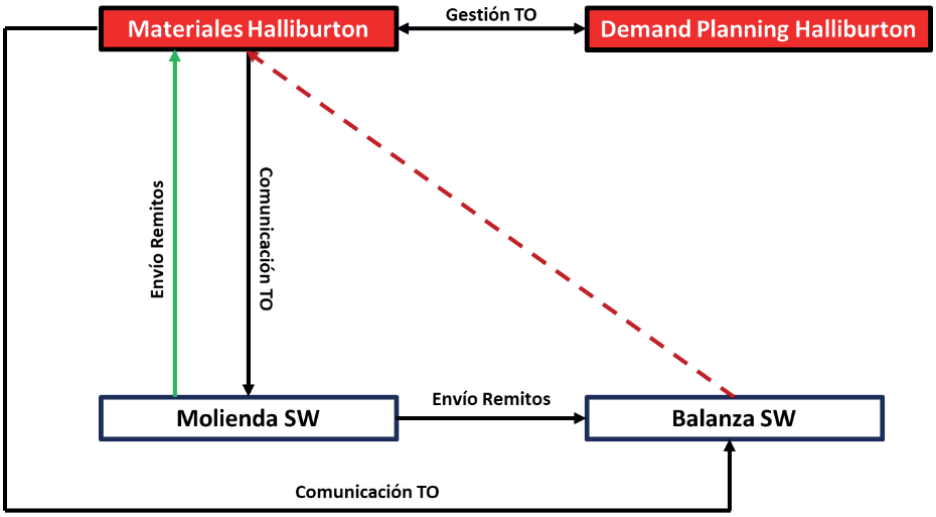
2.4. Detección en el proceso de potencial mejora

Respecto al proceso, se detecta que en el punto 3 un potencial cambio para mejorar el proceso: los remitos físicos se envían a Balanza por intermedio de alguno de los operarios de los molinos. Una vez hecho esto, personal de la Balanza los escanea y los sube al sistema para que personal de Materiales de Halliburton pueda tenerlos a disposición.



2.5. Cambios implementados

La situación actual generaba que los remitos físicos corran el riesgo de dañarse, perderse en el camino u otro motivo que pudiera evitar su llegada óptima a la Balanza. Asimismo, no se enviaban diariamente ya que los operarios no tenían siempre disponibilidad de hacerlo y el tiempo para enviarlos no era siempre el mismo. Muchas veces los llevaban a fin de la semana o a comienzos de la próxima semana, lo que complicaba el procesamiento de estos para personal de la Balanza y la disponibilidad para Halliburton.
Ante esto, a través de intercambios entre las partes afectadas, se detectan posibles cambios que pueden mejorar el flujo de esta documentación, a saber:

1) Principalmente se elimina el flujo de remitos enviándolos por medio de los operarios desde la Molienda hasta la Balanza. La línea punteada color rojo detalla esta anulación (Fig. 4).
2) Personal de Molienda toma el rol de escanear los remitos en la Sala de Control sin que les implique un retraso en sus actividades diarias.

3) Personal de Molienda acuerda con Materiales de Halliburton y Balanza de SW enviar un e-mail con los remitos escaneados, el mismo día que pasan la Orden de Producción. La línea verde detalla este nuevo recorrido (Fig. 4).
4) Halliburton Bahía Blanca acuerda con Halliburton Neuquén realizar un despacho intermedio en vez de realizar un despacho por el total para poder procesar viajes por SAP con mayor agilidad.

Figura 4. Flujo de documentación modificado

3. Resultados

Este pequeño cambio en el flujo de la documentación dentro de la planta se comenzó a implementar en septiembre del año 2020, y tuvo un impacto positivo en el procesamiento de la información, tanto para SW como para Halliburton.

Las principales mejoras se detallan a continuación:

a) Ahorro en distancia recorrida en envío de remitos a Balanza y Materiales.

Proceso anterior: Personal de Molienda debía recorrer una distancia promedio de 500 (metros) contemplando ida y vuelta al sector de Balanza.

Proceso actual: Distancia promedio de 0 (metros).

b) Materiales evita consultar por diferentes medios en reiteradas ocasiones a la Molienda y a la Balanza para que les brinde los remitos.

c) Se evita el manipuleo excesivo de los documentos.

d) Balanza puede cargar los remitos a su sistema de manera más rápida y sencilla.

e) Materiales Bahía Blanca baja el tiempo de procesamiento de la TO.

Proceso anterior: El tiempo de procesamiento promedio era de 10 días.
Proceso actual: El tiempo de procesamiento promedio es de 7 días.

f) Disminución en el tiempo de procesamiento impacta positivamente en el procesamiento de la TO en el destino final [Silos de Barita en Cipolletti, Río Negro].

Proceso anterior: Las TO que se procesaban fuera del mes en el que ocurrían.
Proceso actual: Las TO pueden ingresar dentro del mes que corresponde, dando una visión más real de los números contables.

g) Al procesar menor cantidad de viajes se evita caer en el re-trabajo o reprocesamiento de los documentos. Asimismo, aumenta el control de factores clave como el peso neto de material enviado o el número de TO detallado en el remito, permitiendo detectar errores con antelación y así corregir a tiempo diferencias que pueden producirse en el trayecto.

h) Materiales le empezó a solicitar a Demand Planning que genere la TO por un valor mayor a lo que se pedía con anterioridad. El coordinador de Materiales propuso pasar de 600 (Ton) a 1,500 (Ton). Los despachos de la TO siempre se pueden hacer por encima del valor por el que fue generada la TO pero hay límites para que SAP permita avanzar con el delivery. El objetivo de este cambio es poder realizar el despacho sin esperar que intervenga Demand Planning, al menos hasta que ajuste la TO por exceso o por defecto.

Tabla 1. Cuadro comparativo entre proceso anterior y actual

Concepto	Proceso Anterior	Proceso Actual
Distancia recorrida	500 metros	0 metros
Consulta Remitos	Gran intercambio de mensajes vía e-mail, llamados telefónicos, presenciales	Menor intercambio de mensajes vía e-mail, eventuales llamados telefónicos por alguna omisión
Manipulación Documentos	Varias áreas y personas implicadas (Molienda, Operarios, Balanza)	Solo personal de Molienda maneja la documentación original

Carga de Documentos SW y Halliburton	Lento Balanza debía esperar los remitos físicos desde Molienda	Ágil La carga se produce cuando la Molienda pasa la producción del día
Tiempo promedio procesamiento TO – Planta Barita	10 días	7 días
Tiempo promedio procesamiento TO – Silos Cipolletti	Procesamiento lento Más de un mes para el cierre de la TO	Las TO se pueden procesar dentro del mes, reflejando la realidad
Despachos	Un (1) solo despacho por el total de toneladas Doble trabajo por errores arrastrados Reprocesamiento de TO por SAP	Dos (2) despachos parciales por TO Mayor control de documentos Disminución de errores Correcciones anticipadas

4. Conclusiones

Al desarrollar esta experiencia de cambio dentro de la organización, se puede notar como pequeños cambios pueden generar impactos significativos dentro de un proceso y de una cultura organizacional, para hacerlo más dinámico y eficiente. La flexibilidad y apertura a nuevas formas de trabajo permite construir escenarios propensos a la mejora continua, en cualquier área de una compañía. Adicionalmente, en este estudio de caso particular, tanto cliente como proveedor trabajan in situ, siendo ambos beneficiados con la mejora implementada. Consecuentemente, las mejoras en los procesos correspondientes al proveedor mejoran los del cliente y viceversa. Este concepto tan arraigado a culturas orientales no distingue entre personas, organizaciones, rubros, tamaño de empresas. Es importante detectar puntos de mejora, establecer equipos de trabajo puntuales y desarrollar planes de acción. Aplicar el Ciclo de Deming (PDCA) en cualquier nivel organizacional crea una cultura de mejora continua que desemboca en la búsqueda de niveles elevados de performance en todo campo en el que se implemente.

ICPR-Americas 2020

SEMINARIO DE ENSAYO ESTUDIANTILES

Prefacio

Seminario de Ensayos Estudiantiles ICPR-Americas 2020

Prefacio Este volumen incluye los artículos presentados en el "Seminario de Ensayos Estudiantiles" de la "*Xth International Conference of Production Research-Americas*" (ICPR-Américas 2020), realizado en forma virtual en Bahía Blanca, Argentina del 9 al 11 de diciembre de 2020. Este Seminario fue organizado por un comité organizador local de la ciudad de Bahía Blanca y fue auspiciado por la *International Foundation of Production Research* (IFPR). El Comité local estaba constituido por:

Antonelli María Mercedes (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Barrera Alejandra (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Graff Ana (Dpto. de Ingeniería Química, Universidad Nacional del Sur, Argentina)
Iguacel Nicolás Andrés (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
La Rocca Bruno Humberto (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Monhaiser Francisco (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Oyarzo Paez Leandro Cristian (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Ramburger Camila (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Sobanski Germán (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Cavallin Antonella (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Prieto Germán (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Rango Bruno (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Rossit Daniel (Dpto. de Ingeniería, Universidad Nacional del Sur, Argentina)
Salaberría Florencia (Dpto. de Ingeniería Química, Universidad Nacional del Sur, Argentina)

El Seminario permitió que estudiantes de grado pudieran participar del ICPR-Americas 2020 de forma activa. Para ello debieron escribir un ensayo de entre 1000 y 1500 palabras sobre alguno de los pilares propuestos por el comité organizador. Los pilares fueron: Industria 4.0, Internet de las Cosas, Energías Renovables, Manejo Sustentable de Residuos, Supply Chain Sustentable y/o Economía Circular, Smart City y/o Construcción sustentable. Los ensayos fueron evaluados por los miembros del comité organizador, pudiendo ser rechazados, aceptados con revisiones o aceptados. Luego, los trabajos que pasaron el proceso de revisión se presentaron durante el ICPR-Americas 2020 por sus propios autores. A la presentación de los mismos atendieron distintos investigadores y participantes del ICPR-Americas 2020. Agradecemos enormemente la colaboración y el compromiso de todo el comité organizador, así como de los/as participantes. El Seminario brindó la oportunidad de participar en una conferencia internacional a estudiantes de grado de forma activa y concreta, permitiendo su involucramiento en actividades de elevado nivel académico.

Marzo 2021

Economía Circular: El flujo de información en la Cadena de Suministro

Neri, María Luján

Universidad Nacional del Sur, Bahía Blanca, 8000, Argentina

mlujanneri@gmail.com

Resumen. La administración de la cadena de suministro tiene un papel clave en la reducción de desechos y contaminantes, que las empresas generan como impacto negativo en el medioambiente. La economía circular es un modelo que intenta desvincular el desarrollo económico global del consumo de recursos finitos y propone, junto con un modelo restaurativo y regenerativo, un flujo de información y un flujo de materiales que respaldan la reducción junto con la circularidad. La SC, vista desde una perspectiva integradora, debe subordinar sus diferentes niveles a las nuevas direcciones que entraña esta evolución, valiéndose sus administradores de los sistemas de información para tomar decisiones que orienten los resultados a estos nuevos sentidos. La información, como dimensión que atraviesa la SC en su totalidad, adopta en este cambio de paradigma, un flujo tanto lineal o clásico como circular, que será el pilar para concretar acciones que contribuyan a los puntos fundamentales de esta economía sustentable.

Palabras clave: Cadena de suministro, SC, economía circular, flujo de información.

1 Introducción

La economía circular es el modelo económico estratégico que pretende reemplazar al modelo lineal actual, basado en "tomar, hacer y desechar", o su paralelismo, "comprar, usar y desechar", por uno que tiene como objetivo final ser restaurativo y regenerativo. Este concepto introducido en 1989 por David W. Pearce y Robert K. Turner en su trabajo "Economics of Natural Resources and the Environment", no ganó demasiada popularidad en aquel tiempo, en comparación a los conceptos de "Eco-eficiencia" y "Las tres R" –reducir, reutilizar y reciclar-. Las compañías tomaron conciencia de la creciente preocupación por el medio ambiente, anexada a la consecuente difusión en estos dos términos, y no tardaron en adoptar la premisa de que menos era mejor. De esta manera, a finales del siglo XX, las empresas consiguieron ahorrar en costos y obtener mayores beneficios mediante una reducción de recursos, uso de energía, emisiones y desperdicios, disminuyendo los daños colaterales de sus actividades, al mismo tiempo que su imagen pública mejoró [1]. Sin

embargo, no pareció presentar un gran cambio en sus estructuras, y ¿acaso la reducción de desechos elimina la continua generación de los mismos?

De forma adicional a los objetivos ambientales en común que pudieran tener estas concepciones, la economía circular reconoce que reducir no es una solución a largo plazo, e innova tomando como eje central de la estrategia, una desvinculación de los recursos naturales finitos, con punto de partida en el diseño de los productos y los procesos.

La cadena de suministros, que abarca todas las actividades relacionadas con el flujo y transformación de bienes, desde la etapa de la materia prima hasta el usuario final, en este nuevo modelo mantiene su rol principal. Los materiales y la información, que fluyen en sentido ascendente y descendente [2] en la cadena de suministros adquieren en el sistema circular nuevas direcciones. Por ende, será sustancial en este escenario reforzar al máximo el control y la subordinación de la SC, a la obtención de los nuevos objetivos ambientales que sobrepasan el mero beneficio económico. Una mejor administración del flujo de información será sustancial para lograr la efectividad en las operaciones consecuentes a estas metas.

2 La economía circular y el flujo de información

2.1 Definición de Cadena de Suministro

Las definiciones en torno a la cadena de suministro, según la literatura y dependiendo del enfoque, han sido diversas a lo largo del tiempo. En general, el flujo de materiales ha logrado ser el centro de este concepto, o al menos, el elemento de rápida asociación del mismo. Sin embargo, se vuelve necesario distribuir la atención a las otras dimensiones de SC, que no sólo están constituidas por los distintos tipos de flujo (material, información y dinero), sino también por un horizonte de tiempo (estratégico, táctico y operacional), ambos relacionados de forma simultánea con los diferentes centros de decisión tales como transporte, inventario y locación [3]. El flujo de información será entonces, la base donde se apoyarán las decisiones y relaciones entre el resto de elementos y dimensiones de la SC.

2.2 Marco ReSOLVE

La fundación Ellen MaCArthur, cuya meta es promover la economía circular, propuso junto a la compañía McKinsey & Co, el marco ReSOLVE. Este marco hace de guía para las empresas que pretenden avanzar hacia este modelo circular, y se compone de seis acciones: Regenerate (regenerar), Share (compartir), Optimise (optimizar), Loop (bucle), Virtualise (visualizar) y Exchange (intercambiar) [4]. Al conocer que estas acciones implican conductas tales como incrementar rendimientos y eficiencias de los productos, eliminar residuos en la producción y en la SC, utilizar la automatización, refabricar productos y componentes, reciclar materiales, cambiar transporte clásico a multimodal, entre otras, la importancia del flujo de información toma mayor relevancia.

2.3 Beneficios para la empresa en la Economía Circular

Según algunas investigaciones realizadas por la fundación y la consultora McKinsey & Co entre 2013 y 2015, algunas oportunidades de beneficios incluirían una reducción del costo de fabricación de celulares, que podría disminuir en hasta un 50% por dispositivo, si la industria fabricase teléfonos más fáciles de separar, facilitando el ciclo inverso y ofreciendo algún incentivo a los clientes para devolver los teléfonos [5].

Por otro lado, las lavadoras de alta gama, resultarían más accesibles para la mayoría si se alquilasen en vez de venderse, y según las investigaciones, los clientes ahorrarían aproximadamente un tercio por ciclo de lavado y el fabricante ganaría en torno a un tercio más en beneficios [5].

Además, en Reino Unido, cada tonelada de ropa recogida y reutilizada podría generar unos ingresos de 1975 USD, o un beneficio neto de 1295 USD si se reutilizan en la industria textil [5].

2.4 Análisis del flujo de información en la Economía Circular

Un conocimiento integrado de las diferentes dimensiones de la SC, que responda a cuestiones tendientes a encontrar errores y posibles mejoras, a lo largo de cada proceso de operaciones (planeación, fuente o proveedores, manufactura, entrega y devolución) [6], será clave para conquistar las acciones propuestas.

La planeación, constituye una función principal para conseguir los objetivos principales de esta economía; “reducir” y “devolver”. Debido a que este proceso, tanto en el modelo lineal como en el circular, se nutre de datos históricos, se vuelve necesario procesar información de tiempos estándares, rutas, distancias, capacidades y otros, para lograr una eficiente operación. Recursos como modelos y redes de distribución, que utilizan algoritmos o métodos de programación lineal, pueden mejorar la eficiencia de transporte y entrega, reduciendo así, los viajes y las consecuentes emisiones de gases contaminantes al medioambiente.

La información es y será la piedra angular para la toma de decisiones que determinarán desde niveles de inventario hasta posibles perfeccionamientos en la productividad de máquinas y operarios, que es y seguirá siendo un aspecto clave en la reducción de desechos. En la manufacturación, las herramientas adecuadas incluyen desde sistemas de visualización de información de plantillas de trabajo de operario, hasta cálculos de tiempos estándares destinados a incrementar productividad mediante estudios de movimientos, tal como en el modelo lineal, pero planeando la eficiencia desde el diseño. En el caso de los dispositivos celulares, deberá tenerse en cuenta una base de diseño que permita la reutilización. De esta forma, se supone un flujo de información que se dirige desde los resultados de procesos productivos y funciones posteriores hacía los procesos iniciales de la SC, vinculado a la producción y al diseño. Esta dirección, central en el modelo actual, será igual de importante en la economía circular. En adición, será necesario despegarse del punto de partida de materiales vírgenes o componentes diseñados para un modelo particular.

La información que fluye por la S llega a la devolución, que en el modelo clásico significaba el retorno de productos fallados, y en el nuevo sistema considera el reingreso de productos o componentes en desuso que podrían ser reutilizados, como en los ejemplos de dispositivos celulares o ropa reciclada. De esta forma, se manifiesta la necesidad de un mayor seguimiento de los bienes comercializados, luego de la función de entrega. En esta cuestión herramientas como sistemas de información pueden apoyar las decisiones de localización relacionadas a los centros de devolución. Así pues, el flujo de información se extiende a lo que podrían ser puntos de recogida, y se puede plantear que esta estructura circular introduce, a su vez, un requerimiento de "devolución de la información", que incluye la importancia del conocimiento en instancias posteriores a lo que se consideraba como límite final de la SC.

Por otro lado, el flujo de información a través de la cadena de suministro, debe alcanzar también a los servicios y relaciones vinculados a los clientes. Como punto de partida, la adopción de una estrategia sustentable crea valor y genera un cambio en la percepción de los clientes. No obstante, este nuevo modelo requiere de una relación con el cliente, de mayor durabilidad y confianza que el vínculo requerido por el modelo lineal. Debido a la evolución de un sistema basado en "built in obsolescence", a un modo de fabricación "built in durability", la dependencia de clientes a empresas y viceversa, implica otra reestructuración. Por lo tanto, la información debe fluir también, desde los consumidores hacia las empresas, para ser considerada en las decisiones que las organizaciones tomen.

3 Conclusión

La evolución a la innovadora economía circular implicará no solo circularidad de flujo de materiales, sino un flujo circular de información. El procesamiento de datos no tendrá como principal finalidad mejorar la eficiencia de las operaciones de manufactura, sino que deberá ir más a allá de lo que el modelo lineal consideraba como límite final de la cadena de suministro. Esta circularidad entraña un cambio de paradigma en la administración de este flujo, y de la dimensión de flujos en general. Por lo tanto, deberán integrarse a través de sistemas de información, todas las funciones y elementos de la SC, de la misma forma que en el modelo clásico y añadiendo nuevas direcciones, que impliquen tanto la reducción como la devolución. Adaptando el uso de la información a estos nuevos sentidos, podrá cumplirse de forma simultánea un compromiso con el objetivo sustentable y un triple objetivo económico, social y ambiental.

pereyratm7@gmail.com

Resumen. El calentamiento global es uno de los mayores problemas ambientales presentes en la actualidad. Aún con las medidas que se han tomado hasta el momento, queda un largo camino por recorrer para lograr revertir los daños causados por dicha cuestión. Una de las medidas más acertadas es la sustitución de los hidrocarburos como fuente de energía por el uso de fuentes 'naturales' o 'renovables'. Es vital el compromiso de todos y cada uno de nosotros para lograr un mundo más limpio.

Palabras claves: Energías limpias, renovables, acuerdo de París.

1 Introducción

Desde finales del siglo XVIII y hasta mediados del siglo XIX el mundo sufrió una serie de cambios que alternaron completamente el estilo de vida como se conocía hasta el momento. De la mano de la revolución industrial se vivió una de las transformaciones socioeconómicas más importantes de la historia de la humanidad, dejando atrás una vida rural basada casi por completo en la agricultura y la ganadería, dando lugar a una vida urbana, con la economía industrializada y mecanizada.

La invención de las máquinas de vapor para la industria textil, pasando por la iluminación doméstica, y así como el uso de miles de kilómetros de ferrocarriles, fomentaron el uso de hidrocarburos como fuente de energía a nivel mundial. Con el paso de los años, este consumo vio un crecimiento exponencial de la mano de los derivados del petróleo y la aparición del gas natural en la matriz energética [1].

Este consumo masivo de hidrocarburos derivó en lo que hoy en día conocemos como calentamiento global, producido por los gases de efecto invernadero (de aquí en más, GEI). Los principales GEI son el vapor de agua (H2O), el dióxido de carbono (CO2) y el metano (CH4) [2]; dichos gases pueden obtenerse con la combustión de los hidrocarburos presentes en el petróleo, el gas natural, el carbón, entre otras. El calentamiento global aumenta la temperatura superficial del planeta Tierra a velocidades alarmantes, efecto que se ve evidenciado en el súbito derretimiento y desprendimiento de glaciares y la consecuente elevación del nivel del mar [3].

A pesar de que algunas consecuencias del calentamiento global ya son irreversibles, no es tarde para alivianar las que aún están por venir. Para esto, naciones de todo el mundo firmaron el Acuerdo de París, dentro del marco de la Convención Marco de las Naciones Unidas sobre el Cambio Climático. Dicho acuerdo se basa, principal-

mente, en ‘‘reforzar la respuesta mundial a la amenaza del cambio climático manteniendo el aumento de la temperatura mundial en este siglo muy por debajo de los 2 grados centígrados por encima de los niveles preindustriales, y proseguir los esfuerzos para limitar aún más el aumento de la temperatura a 1,5 grados centígrados’’ [4]. Al ser un objetivo ambicioso, los organismos gubernamentales han de buscar las mejores alternativas para cumplir con lo estipulado en el Acuerdo.

El objetivo de este ensayo es presentar el panorama actual de las energías renovables, su importancia y su proyección a futuro.

2 Desarrollo

Considerando que tres de los principales GEI son producto de la combustión de hidrocarburos, no es difícil suponer que encontrar una alternativa eficiente y rentable a éstos favorecería las condiciones ambientales en donde se apliquen. Por eso, la mayoría de los países participantes de la Convención Marco de las Naciones Unidas sobre el Cambio Climático apuestan fervientemente al uso de Energías Renovables.

Se denomina Energía Renovable a ‘’aquellas fuentes energéticas basadas en la utilización del sol, el viento, el agua o la biomasa vegetal o animal -entre otras-. Se caracterizan por no utilizar combustibles fósiles…’’ [5]. Entonces, una energía renovable es aquella energía que se obtiene de fuentes naturales, que son capaces de regenerarse por sus propios medios o que contienen una inmensa cantidad de energía que, a fines prácticos, se considera inagotable. Las principales energías renovables son:

- la energía **eólica**, aprovechando la energía cinética del viento;
- la **geotérmica**, aprovechando el calor transmitido desde el interior de la Tierra;
- la **hidroeléctrica**, aprovechando la energía cinética y potencial de los cuerpos de agua;
- la **mareomotriz**, similar a la hidroeléctrica, aprovechando las mareas de los mares;
- la **solar**, aprovechando la radiación electromagnética procedente del Sol;

- la **biomasa** y los **biocombustibles**, materia orgánica utilizable como fuente de energía;
- la **energía nuclear**, energía que se libera espontánea o artificialmente en las reacciones nucleares;

En los últimos años, la obtención de energía mediante estas fuentes tuvo una evolución muy favorable. Alentadas por las altas emisiones de GEI, la producción de energías renovables crece un 7.1% anual, representando más de la mitad del crecimiento en energía global. Como se presenta en la siguiente figura, estas fuentes constituyen hoy en día un 4% de la matriz de energías primarias, y se espera que para 2040 representen un 15% de la misma [6].

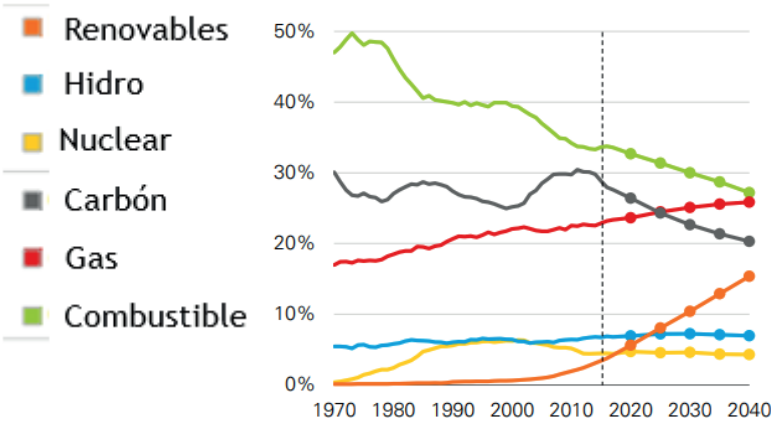

Fig. 1. Porcentaje de consumo de energía por distintas fuentes

El auge de las fuentes limpias y los rápidos avances tecnológicos trajeron con sigo una reducción de costos en los equipos necesarios para el desarrollo de estas, lo que favorece aún más el panorama ambiental para los años venideros. Las principales tecnologías renovables –como la eólica y la solar fotovoltaica- están reduciendo drásticamente sus costes, de forma que ya son competitivas con las convencionales, no solo para organismos gubernamentales o empresas multinacionales, sino también para el uso doméstico.

Por supuesto, la elección de la fuente de energía alternativa depende fuertemente de las condiciones geológicas y climatológicas del lugar. Por ejemplo, Uruguay invierte cerca de un 3% de su Producto Interno Bruto en una reforma estructural para alcanzar una conversión completa a energías limpias; dicha inversión logró que en 2019 el país funcionara en un 98% con energías renovables, siendo la hidroeléctrica y la eólica las preferidas por los uruguayos.

Argentina, a pesar de que todavía está lejos de alcanzar una independencia energética con respecto a los hidrocarburos, cuenta en su matriz con diversas formas de energía renovable. Según el balance energético nacional, desarrollado por la Secretaría de Energía de la Nación, la producción de Energía Hidráulica se encuentra en mayor proporción con aproximadamente 3 millones de TEP (Toneladas equivalentes de petróleo), seguida por la producción de Energía Eólica, con aproximadamente 559 miles de TEP. La Energía Solar no se encuentra muy presente en el país, produciendo sólo 69 miles de TEP. Es importante mencionar la contribución de la Energía a partir de biomasa (bagazo, leña, etc.) y biocombustibles (aceites y alcoholes vegetales) a la matriz energética, ya que, en conjunto, aportan cerca de 4,6 millones de TEP. Vale la pena mencionar que Argentina cuenta con potencial para producir Energía Nuclear, otra forma de energía renovable, pero los peligros que esto puede traer hacen que sea imposible la utilización de dicha tecnología [7].

A pesar de que el Acuerdo de París fue firmado por los gobernantes de cada país, la idea de cumplir los objetivos sólo con inversiones y trabajos públicos es una utopía. Por lo tanto, empresas de carácter privado han realizado su aporte a la causa, así como también lo hace el común de la gente con el uso doméstico de energías limpias, a pesar de la gran inversión económica que esto implica [8].

Los avances tecnológicos y el compromiso, tanto del sector público como el sector privado, presentan un panorama alentador en lo que respecta a la reestructuración energética mundial; aun así, esto tampoco significa que se cumplirá el objetivo, ya que no todo el mundo colabora de la misma manera. Países como Uruguay, Islandia y Noruega lideran la carrera en homogeneizar la producción de energía con fuentes renovables; el problema es que estos países no son los que mayor huella de carbono tienen. Estados Unidos, que secunda el ranking de países con mayores emisiones de CO2 en el mundo [9], decidió abandonar el Acuerdo de París, alegando que las condiciones no eran justas para dicho país, aunque se comprometían a trabajar ‘’para garantizar que Estados Unidos se mantenga como el líder mundial en temas ambientales, pero bajo un marco que sea justo…’’. Así, queda evidenciado que no todo el mundo profundiza la situación de la misma manera, aunque, en rasgos generales, afecte a todos por igual.

3 Conclusión

Considerando el paradigma energético nacional y mundial, se ve que los objetivos del Acuerdo de París son, como se dijo anteriormente, muy ambiciosos. A pesar de todo, se espera que en los próximos años la matriz energética global se encuentre más repartida entre las distintas formas de energías alternativas con respecto a las fuentes convencionales, a causa de las reestructuraciones y políticas de cada país, así como con el compromiso ciudadano, que, sin realizar una inversión de gran envergadura, puede aportar su grano de arena, reduciendo el uso del automóvil y los ascensores fomentando la bicicleta, la caminata y el uso de escaleras, respectivamente; también con la regulación de distintas actividades cotidianas que probablemente sean resultado de malos hábitos y costumbres, por ejemplo, ducharse por más de 5 minutos, prender las hornallas o el horno para aclimatar la habitación, el uso de aires acondicionados a temperaturas muy bajas, entre otras cosas.

La Tierra es una sola, y sin el compromiso de todas las partes, en poco tiempo el daño será irreversible. Está en cada uno hacerse cargo y tomar cartas en el asunto, o cruzarse de brazos y ver como el planeta se deteriora completamente.

‘’Cambiar a energías renovables, no es sólo la mejor opción. Es nuestra única opción’’ [10].

Construcción sustentable y smart city

Carolina Ailen Sepulveda[1]

[1] Universidad Nacional del Sur, Bahía Blanca CP 8000, Argentina
carosepulveda99@gmail.com

Resumen. La industria de la construcción es una de las más contaminantes en la actualidad, presentando valores de emisión de gases y consumo de energía alarmantes. Si bien hasta el momento se han realizado numerosos avances y mejoras en la producción, todavía hay un gran camino por delante hacia una construcción más sustentable, con menor huella medio ambiental y la posibilidad de desarrollar el concepto de "Smart city" alrededor del mundo.

Palabras claves: Smart city, construcción, huella medio ambiental.

1 Introducción

La industria de la construcción tradicional tiene un importante impacto ambiental debido a la emisión de contaminantes atmosféricos, como los gases de efecto invernadero, y el gran consumo de energía. Además, los residuos provocados durante el proceso terminan contaminando tanto los recursos hídricos como el mismo aire que respiramos.

Mediante alternativas en los materiales de construcción, políticas e incentivos gubernamentales y cooperación entre los distintos sectores y la comunidad es posible disminuir la huella medio ambiental de la actividad y generar una mejora en la calidad de vida de las personas.

2 Desarrollo

2.1 Origen

Los principales impactos ambientales de la construcción tradicional son la emisión de contaminantes atmosféricos y el gran consumo de energía. Aproximadamente el 40% del consumo total de energía es causado por esta actividad a nivel global.

En el siguiente gráfico se muestra el porcentaje de emisiones de CO2 derivadas del consumo de combustible según el sector productivo. Se observa un alto porcentaje (38,6%) por parte de la industria manufacturera y construcción.

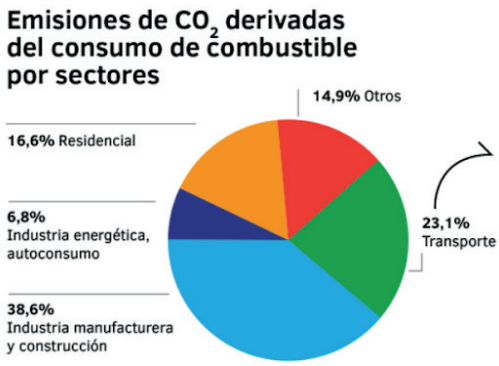

Fig.1. Emisiones de CO2 derivadas del consumo de combustible por sectores [6].

Además de los GHG se encuentran los contaminantes CAPs (Criteria Air Pollutants), grupo conformado por partículas en suspensión, óxidos de azufre y nitrógeno (SOx y NOx), monóxido de carbono y compuestos orgánicos volátiles; principales contribuyentes al smog y lluvia ácida. Los equipos de construcción generan una enorme cantidad de PM2.5 (partículas en suspensión de menos de 2.5 micras) y NOx, contaminantes influyentes en el asma, cáncer de pulmón, enfermedades cardiacas, cambio climático y el deterioro de la capa de ozono [2].

Por otra parte se encuentra la contaminación de recursos hídricos y los problemas de salud que genera. Se estima que millones de personas mueren cada año como consecuencia de enfermedades infecciosas transmitidas por el agua. El cambio climático agrava la situación .Se prevén sequias, olas de calor, inundaciones y tormentas más fuertes.

Centrándose en la construcción, se ve que durante el siglo pasado el hormigón/cemento fue el material más comercializado debido a su versatilidad, rendimiento, disponibilidad y bajo costo de materias primas; sin prestar atención a su impacto en el medio ambiente. Sin embargo, se espera que la demanda se incremente en regiones en desarrollo como India, Medio Oriente, Sudamérica y África; donde la urbanización se hará cada vez más presente [3].

2.2 Industria de la construcción

El trabajo de construcción en espacios abiertos y al aire libre genera de manera directa una gran cantidad de emisiones CAPs y polvo de la erosión de suelo, trituración de rocas y demolición de edificios (emisiones fugitivas).

Por otra parte, la implementación de un sistema sostenible se dificulta debido a la descentralización de la actividad, lo que obstaculiza la cuantificación precisa de sus impactos ambientales. Además de que la mayoría de las firmas de

construcción son pequeñas, como ningún proceso se repite en iguales condiciones que otro anterior no es posible comparar y juzgar una mejora en la gestión ambiental.

En esta situación se vuelve imprescindible desarrollar un método confiable y seguro para evaluar las emisiones en los procesos de construcción. En la actualidad se presentan dos metodologías: LCA (Evaluación del Ciclo de Vida) e EI-O LCA (Evaluación económica del Ciclo de Vida). El LCA evalúa efectos ambientales de edificios comerciales y residencias, desde la extracción de la materia prima hasta el mantenimiento y el final de la vida útil del lugar. Sin embargo, en su mayoría de aplicaciones se pasa por alto o se aborda incorrectamente el impacto ambiental de los procesos involucrados. El segundo método, EI-O LCA utiliza información de sectores separados y evalúa la interacción económica en dichos datos.

Otra parte importante es el trabajo con las empresas y la posibilidad de adoptar un modelo más ecológico. Para esto existen dos tipos de incentivos: programas de subvenciones y financiación directa para reemplazar equipos viejos por otros más nuevos y limpios, y en segundo lugar incentivos fiscales para incentivar el uso de tecnologías y disminuir las emisiones [2].

Actualmente, la construcción sustentable y los materiales de construcción con una huella medio ambiental reducida atraen el interés en la industria de la vivienda y construcción a nivel global. Gracias a esto se generaron cambios y avances beneficiosos para el ambiente tales como:

- Desarrollo de hormigón de geopolímeros de espuma con un mayor rendimiento y disminución en el consumo de energía y emisiones.
- Mejora de la eficiencia energética en plantas de manufactura.
- Uso de biocombustibles.
- Reciclado de residuos de construcción y demolición.

2.3 Nano sensores y avances tecnológicos

El rápido crecimiento del "Internet de las cosas" (Internet of things) abre nuevas posibilidades para la recopilación de datos urbanos de manera sencilla y segura. El IoT es un sistema que permite que los objetos sean controlados y detectados de manera remota a través de redes de infraestructura existentes. A partir de él surgió la idea de desarrollar el IoS (Internet de los sensores) capaz de monitorear en tiempo real los ambientes urbanos, a través de los parámetros necesarios y significativos. Algunas de las posibles aplicaciones del sistema serían: relojes inteligentes con datos locales de contaminación, redes de agua con auto diagnóstico de fugas o contaminación ambiental y sistemas de aire acondicionado que optimicen la calidad del aire [1]. Dentro de las ciudades las comunidades están comenzando a implementar cambios prácticos como reducción de la velocidad en las principales carreteras, reducción del tráfico pesado, multas por contaminación sonora y apoyo a los sistemas de transporte público y la movilidad

alternativa o verde. A su vez se ha comenzado a indagar sobre el concepto de ciudad sensitiva (Sense-city), que permitiría que la ciudad se auto diagnostique de manera constante con el fin de preservar el medio ambiente, ahorrar recursos y proteger a sus habitantes. Este proyecto se basa en la implementación masiva de micro y nano sensores en escenarios urbanos reales profundizando nuestro conocimiento acerca de su funcionamiento y dinamismo. Algunos de los puntos principales son:

- Desempeño energético de edificios y vecindarios.
- Infraestructura para la compilación de datos urbanos.
- Identificación por radio frecuencia (RFID) usado en monitoreo de la ciudad.
- Mapeo de contaminación.
- Carreteras foto-voltaicas.

2.4 Aplicaciones en América Latina

Unos de los ejemplos concretos de construcción sustentable y ahorro de recursos en América Latina es el museo denominado "Museo del mañana", ubicado en Rio de Janeiro, Brasil. Este edificio se define como autosuficiente y sostenible, rodeado por áreas verdes y estanques de agua. El techo, por otra parte, está compuesto por placas fotovoltaicas que cambian de posición durante el día en busca del mejor aprovechamiento del recurso.

Fig.2. Museo del mañana, Rio de Janeiro, Brasil [5].

Otro ejemplo para destacar es el edificio del Instituto del Fondo Nacional de la Vivienda para los Trabajadores (Infonavit), ubicado en Ciudad de México, donde se construyo la azotea verde más grande en la región. Este lugar, además de usarse como esparcimiento laboral, presenta una gran variedad de especies vegetales y un espacio donde se producen alimentos orgánicos [4].

Fig.3. Terraza edificio central Infonavit, Ciudad de México, México [4].

3 Conclusión

A partir de los datos e información indagados en el ensayo se ve una gran mejoría en la industria de la construcción y vivienda, habiendo empezado a implementar el uso de biocombustibles, generar materiales alternativos, facilitar a los propietarios el acceso a maquinaria nueva y menos contaminante, entre otras. Si bien hay un gran camino por recorrer para generar una conciencia responsable acerca de lo que la contaminación puede provocar en el medio ambiente y la salud de las propias personas, los avances son importantes y dan pie a nuevos cambios a futuro.

Las ideas y trabajos deben enfocarse no solo en mejorar la situación actual, sino permitir a generaciones futuras vivir en un mundo equilibrado y con buena calidad de vida.
